The following general principles may be laid down in determining the length of time the stone may be allowed to remain in the ureter

FIG 3—A, Stone in ureter, 11 cm above the bladder. B, the filiform tip of the device is seen to pass by the stone. C, the rubber bag inflated with opaque solution just below the stone. D, the catheter

1 If the stone is situated in the upper or middle part of the ureter, and following two or in the most three consecutive fruitless attempts to pass by the obstruction with catheters and the

FIG 4—As compared with Fig 3, most of the inflation took place not laterally but in a longitudinal direction, pushing the stone (arrow) upward for 4 cm. This bag was tied only at its proximal end. Patient passed the stone

failure of the stone to show any tendency to move, an open operation is indicated, even in the absence of infection and the apparent presence of drainage through channelization

2 If the obstruction has been passed, the stone being in the upper or middle part of the ureter, and it is apparent that the functional activity of the kidney has been improved and the infection combatted, one should wait a little longer, even if the stone has not moved. It is in these cases that leaving one or more ureteral catheters in the ureter for considerable length of time, as advocated by Buerger² and, more recently, by Beer and Hahn,³ has resulted in the loosening up of the calculus

3 The downward movement of the stone even for a fraction of an inch as determined by roentgenograms, is presumptive evidence that encapsulation of the calculus has not taken place, and one may with reasonable certainty expect the stone to come further down. Treatment should be vigorously pursued in these cases, lest the stone becomes tightly impacted or encapsulated

4 It is when the stone is situated in the lower ten centimeters of the ureter that the advisability of prolonged waiting should be emphasized, even though the stone may appear to be hopelessly impacted, provided, of course, renal infec-

FIG. 5A—The rubber bag inflated with opaque solution is shown here below a fair sized stone (arrow) in the right ureter 4 cm above the bladder. Patient gave a history of having had attacks of renal colic for four years. Many previous attempts by other cystoscopic methods failed to bring this stone down and the patient was advised an operation.

FIG. 5B—Same case. Twenty minutes later. The stone descended to a point almost within the intramural portion of the ureter. Patient passed the calculus.

tion or other emergency is excluded. The five operative cases in which the stone was situated in the lower one third of the ureter were all badly neglected cases of old standing when the stone was allowed to remain in the ureter for years, either through the failure to recognize the condition or the unwillingness on the part of the patient to have the stone removed. Two of these

cases had bilateral calculous obstruction and were threatened with uremia, so that the operation was not a matter of choice but emergency. The results so far obtained have sustained me in my firm belief that practically every case of stone in the lower end of the ureter is amenable to its removal by intraureteral manipulations, by methods which were described in my previous publications on this subject.^{4,5} There are cases in which the stone has reached such an enormous size that its removal by cystoscopic means is a matter of me-

FIG. 6—Dilatation of the uretero-pelvic junction with the rubber bag for a small pelvic stone. Patient is still under treatment.

chemical and anatomical impossibility. Those cases, however, are so badly neglected that removal of the obstructing calculus is of no practical importance, as only a nephrectomy will solve the problem.

The most essential factor in the treatment of calculi situated in the lower third of the ureter is dilatation of the ureter below the obstructing stone. The nearer the degree of the dilatation conforms to the size of the stone the better are the prospects of its removal. Ordinary ureteral catheters do not produce sufficient dilatation, especially when the stone is large. In the past few years gradual dilatation of the ureter up to 20 F was produced with the aid of tunneled bougies, which the author devised a few years ago.⁶

Recently I began to use rubber bags for dilating ureters instead of the bougies as it allows dilata-

⁶ Manufactured by Wappler Electric Co. in New York City.

FIG 7A—Dr Leo Buerger of New York was good enough to permit me to use these interesting films in a successfully treated case. This figure shows the inflated bag after it was passed beyond the stone

FIG 7C—Same case Dilatation of ureter below the stone. The dilatation was so effective that with the use of the usual methods advocated by Dr Buerger, successful expulsion took place at a later date.

tion to almost any size that is desired, enabling the passage of large sized stones. The principle involved is the same as in the use of rubber bags for dilating the uterine cervix in labor, or the use of the bags for dilating oesophageal strictures

FIG 7B—Same case By bringing down the bag, actual dilatation of ureter was accomplished alongside of the stone

The method has not been hitherto used on human beings although experimentally it was used on animals by Illewitz.⁷ The detailed description of the device, its indication and technique, was pub-

lished in the *Journal of Urology*.⁸ Suffice it to say here that it consists of a rubber bag, made to fit the smallest author's tunneled bougie, or an all woven catheter made especially for this purpose by C R Bard, Inc, which is much smaller in calibre, more flexible and easier of introduction. When the bag is introduced into the ureter the distension of the bag is produced by injecting some opaque solution through the proximal end of the catheter-bougie so that roentgen ray shadows could be obtained, bringing out definitely the extent of dilatation and the relation of the distended bag to the stone. Air should not be used as it is impossible to determine the exact amount introduced on account of its compressibility and leakage. Although the number of cases in which the rubber bag was used is not sufficiently large to draw any definite conclusions as to all of its possibilities, I am inclined to believe from the results so far obtained, that in this device we have a valuable addition to the present methods of intra-ureteral manipulations for removing stones. The original report included six cases of stone in the ureter, all of them situated in the lower segment, most of them stubbornly impacted, resisting previous methods of treatment, in which expulsion of the stone followed dilatation of the ureter with the rubber bag. Since then the rubber bag was used on eight more cases with same results.

The device used in the earlier phase of this work consisted merely of a rubber bag covering the tip of a catheter and tied only at the proxi-

mal end. Experimentally⁹ it was found that by inflating this bag, lateral dilatation could be produced only to a limited degree. The moment a certain point of the ureter distensibility was reached, the inflated bag would expand in the line of least resistance, that is, in the upward direction

place in a downward direction. This observation was corroborated clinically. In a few instances, the bag, after distending the ureter to a certain degree, would expand in a longitudinal direction and push the stone upward (Fig 4), sometimes for a considerable distance. A new rubber bag catheter (Fig 2) was then devised in which both ends of the bag were tied. On inflation, the entire force is directed only laterally, which makes this bag an ideal dilating agent. The new device is also provided with a filiform tip which renders its introduction into the ureter much easier. Ac-

FIG. 8C—Same case. Further descent of the stones following the above dilatation

knowledge is hereby made to Mr C R Bard and his associate, Mr J F Willits, for their tireless cooperation in this work.

The objection that is often raised to repeated cystoscopic manipulations is that they may result in infection. My own experience has taught me that kidney infection directly attributable to catheterization is comparatively rare. The patient may develop a severe constitutional reaction following intra-ureteral manipulation, but in such cases there was a pre-existing infection. On the contrary, abatement of infection and improved kidney drainage has resulted from passing catheters into the kidney, as in the majority of cases it was possible to pass by the obstruction. Many kidneys have been saved by this procedure. As has been stated before, the low percentage of kidney infection as an end result of ureteral obstruction was attributable to repeated instrumentation which resulted in better drainage. In many cases this was the factor which has decided in favor of continuance of the conservative measures. One should be able to manage the cases until the stone has been removed either

FIG. 8B—Same case. The ureteral stone has descended, following dilatation with a rubber bag, to a point 12 cm above the bladder. One of the pelvic stones "took a free ride" and both stones can be seen just above the inflated rubber bag.

When the ureter above the bag was tied by a ligature, recession of the inflated bag would take

by operation or through cystoscopic route, without subjecting the kidney to real jeopardy, by constant surveillance and use of proper judgment in the possibilities of the case. The kid-

FIG 8E—Same case. Two days later. Stones in the intramural portion of ureter, ready to pop out.

neys have remarkable recuperative power, once the obstruction is removed, the return of its function to normal and spontaneous abatement of infection, unless accompanied by destruction of parenchyma is, as a rule, very rapid.

CONCLUSIONS

1 Kidney drainage is maintained by urine burrowing a linear groove or channel on the surface of the calculus in about 30 per cent of impacted ureteral stones.

2 Mulberry calculi, or those studded with spiculi, owe their configuration to urine burrowing its way to bladder all over the surface of stone. (These calculi were not considered in estimating the percentage of the above group.)

3 Attacks of renal colic are undoubtedly due to clogging of the grooves, thus producing acute retention.

FIG 8F—One kidney stone shown in Fig 8A still remains in the pelvis of the kidney.

4 The presence of an apparently hopelessly impacted stone in the lower ureteral segment, even for a considerable length of time, should not be viewed with undue alarm, if renal infection is excluded.

5 The principles laid down in management of ureteral calculi, in absence of kidney infection, are based upon the position of the stone.

6 Fifty-four per cent of stones impacted in upper part of ureter in this series of cases were removed by open operation, while 93.6 per cent of stones in lower part of ureter were amenable to removal by cystoscopic manipulation.

7 Ample dilatation of the ureter below obstructing stone is essential in attempting to remove the stone. This was produced by the author's tunneled bougie.

8 The rubber bag method in dilatation of ureter may prove to be a valuable aid in the treatment of ureteral stones.

A PLEA FOR THE MORE RATIONAL MANAGEMENT OF THE UNDER-NOURISHED CHILD*

By FRANK VAN DER BOGERT, M D, SCHENECTADY, N Y

THE management of the undernourished child is still a problem

The interpretation and clinical application of the more recent knowledge of nutrition have apparently failed to take into account two very important and, I think, unquestioned facts that the size of the individual is not an infallible index of his health and that it is not the amount of food ingested, however rich in essential constituents, which determines physical development

The real fault is the management of these children seems to lie in the effort, at least upon the part of the lay worker, to make all children conform to a weight and height standard, a standard which has been proven unreliable by several investigators including Dublin and Gebhart, who, corroborated by others, have shown that the use of the tables fails seriously in selecting the undernourished. From two-fifths to three-fourths of their series, though conforming to generally accepted standards of weight and height were shown upon careful physical examination to be defective. These observations point to a very real error in the direction of overlooking ill health in the child of so-called normal weight for height but may also be interpreted to mean that the result in gain of weight shown after high calorie feeding cannot in itself be considered as evidence of improvement. Furthermore, there are still some of us who believe that there are hereditary factors to be taken into account. Personally, I cannot but feel that the American child, a conglomerate of many racial stocks, must to a certain extent be influenced by inherited traits. Certainly biology teaches us that stature is inherited.

There is, of course, danger of laying too much stress upon the so-called family build, but it is unjust to brand its consideration as an attempt to establish an alibi to save the reputation of the doctor when he fails in his efforts to correct an undernourishment problem.

Owing to our desire to make all children conform to standard, the tendency has been to depend upon a method of management, the principles of which are unquestionably basically wrong, namely, that so far as diet is concerned, undernourishment is always primarily due to a deficiency in food intake and that food essentials swallowed in sufficient amount can prevent and remedy the defect. No better illustration of the fallacy of this belief can be cited than the result of the study of Xeroph-

themia and Keratomalacia by Block among the children of Norway during the war. Block found it impossible to explain the presence of the disturbances in all the cases upon the score of a deficiency of vitamin A in the diet alone. Codliver oil injected into the tissues caused disappearance of the xerosis. The conclusion was reached that xerophthalmia may arise both from an insufficient supply of the essential in the food and from conditions of the digestive tract which hinder assimilation of the factor.

What has been termed the newer knowledge of nutrition has caused so much stress to be laid upon food values and vitamin requirements that forced feeding has become the generally accepted method of treatment and little consideration has been paid to the ability of the digestive tract to do its part in conversion and assimilation. The trite but very apt analogy of the furnace has been forgotten and fuel that is absolutely unburnable is expected to produce heat and power. The efforts of the nutrition worker have resolved themselves into an attempt to force the estimated number of calories, vitamins and lime salts down the throats of their charges without respect to digestive capacity and often to the destruction of digestive functions. Tempting, coaxing, bribery and deception are resorted to with gain in weight as their only justification, a gain which is by no means always permanent and which in itself is not proof of nutritional improvement.

A standard which must have a far deeper appeal, it seems justifiable to suggest, would be one of general appearance of well being, accompanied or not by a so-called normal weight—height ratio. Such a standard should be practicable in school work and pre-school clinics and applicable by parents, teachers and social workers where thorough physical examination by physicians cannot be obtained. By far the best indices of health in childhood are what we are in the habit of calling "pep", interest in surroundings, whether work or play, lack of tendency to early fatigue, color of skin and mucus membranes, appetite and, above all, a good disposition. Indeed, if one wishes to depend upon a single symptom he will do well to choose the disposition, the reaction to environment. Its improvement, under treatment, means infinitely more than a gain in weight and will invariably be followed by such a gain if the individual is actually below standard. The term "spoil" implies lack of restraint in those things which influence health and nutri-

* Read at the Annual Meeting of the Medical Society of the State of New York, at New York March 31, 1926

tion The spoiled child is, therefore, in most instances a sick child

A steady increase in body development is, of course, to be desired, but unless accompanied by other evidences of improving health the hope of race betterment can never become a realization

The previous histories of severe and distressing cases, severe enough in themselves and distressing enough to the parents to encourage the consultation of a pediatricist, should, it seems, convince the advocate of forced feeding that it is not more food but less that is required These unhappy youngsters have practically all been overfed in their earlier life, their desire for normal food is gone and it is only by pampering and deception that they can be encouraged to eat at all I have been told of a child of about two years who was fed salt herring by its mother in order to get it to drink the amount of milk advocated by the United States Department of Labor and of another whose mother buried a piece of sugar in its baked potato to encourage its consumption I have seen children bribed, tempted, coaxed and even threatened into taking food which they knew instinctively they could not digest I have been told of soft boiled eggs refused yet greedily taken when beaten up with milk and sugar, and I have seen a child of two still being allowed the bottle between meals although apparently consuming plenty of general diet because the mother thought she ought to have the milk and it was the only way that she could get it down

Many as infants have been kept at breast or bottle well into the second or third year, evidence of parental weakness and of the general lack of discipline and restraint Most of them, because of their parents encouraged belief in the life saving qualities of milk have been allowed or encouraged to consume quantities at all times and in all places or have been forced to swallow the amount specified as that which they "should" or "must take in order to obtain sufficient salts and vitamins" and thus at the expense of the appetite for digestion developing foods Quarts of milk are being consumed, egg-nogs swallowed, school lunches served, but, despite the rise of the weight curve if such occurs, the children have remained or have become more unhappy, irritable, generally distressed, pale and languid More milk, more lunches, more tempting and palatable food increase the general discomfort but the effect of reduction of the quantity of food at meals, the elimination of between meals feeding and the absolute ignoring of likes and dislikes will, if persisted in, bring about a change which must convince the most skeptical Almost certainly a loss of weight ensues but the loss is in most cases promptly re-

covered from with an accompanying improvement in the general physical condition It can be safely stated as almost an axiom that food which is not relished is not digested, that a desire for food is essential for the conversion of that food into healthy tissue It seems then that our first care should be for the efficiency of the digestive apparatus, manifested by an appetite for wholesome, unadorned food

There is reason to believe that in late infancy the development of the digestive tract should be carefully encouraged, that food should be given in a form which, though readily digestible requires a certain effort on the part of the child to assimilate it The dangers of prolonged feeding with sloppy food have been demonstrated experimentally with puppies and the effect of prolonged nursing and of long continued bottle feeding illustrate the danger of pampering the digestive tract of the child Children thus fed, do not develop normally, their tissues are flabby, their color bad, and they lack resistance to disease The eruption of the teeth, may, I think, be taken as an indication that the digestive tract has developed to a point where it can make its own emulsions and for this reason I believe with Sim Wallace that the amount of milk at this period should be lessened rather than increased and that the teeth and stomach should be given their work to do At this time, increase of the feeding interval allows for better recuperation of the digestive organs If the feeding interval has been long enough one can feel assured that hunger is real

With proper feeding on a general mixed diet, milk as a vitamin or lime carrier is, I think, not essential Milk is a food prepared by nature for the undeveloped alimentary tract of the infant and in later years development must be normally stimulated Small quantities of milk with the meals are probably beneficial, large quantities, I believe are deleterious Milk is not a necessity to the older child, vitamins and lime salts are supplied elsewhere No animal in its natural existence obtains milk after leaving the mother's breast No one would question the vigor of a lion or tiger in the wild and an elephant develops a tusk two to ten feet long

In order to deal intelligently with the undernourishment problem there must be a fuller appreciation of the fact that undernourishment is not always due to underfeeding, indeed that it is rarely due to underfeeding in the generally accepted meaning of the term and that in most cases ignorance rather than poverty is the underlying cause My own experience has been and my practice is certainly not limited to the rich that overfeeding and irregular eating are practically always responsible and these errors must be combated by another form of

education than is given parents today. Whether it is our fault or theirs, most of them believe that all they need do is to serve more vitamins and calories. They should, of course, be made to appreciate food values and the essential constituents of a balanced diet but in addition they should be taught the necessity of safeguarding the digestion, the dangers of too frequent feeding and of sweet eating, the need of digestive rest and the elimination of waste products and the distinction between the two types of hunger. No matter what the social status of the patient, the history is nearly always the same, irregular, frequent feeding in infancy, the giving of food for the relief of distress or discomfort from almost any cause, consequent failure of appetite manifesting a wrecked digestion, and loss of weight treated by forcing, urging, tempting and bribery. These children have become sweet eaters and even coffee and tea drinkers because of the mistaken idea of the parents that any food is better than none.

Instead of the addition to an already excessive daily ration of more vitamins and salt containing foods the ideal would be a period of almost absolute starvation to relieve the digestive tract temporarily of its burden and to allow recuperation. In practice, however, the absolute withdrawal of food is unnecessary because of the child's refusal for a time to accept the changed condition. With proper control they are soon glad to get and willing to consume the vitamins and salt containing foods which the body requires. Gain in weight produced by such methods must be permanent, the gain of forced feeding is likely to be temporary.

My conception of the proper treatment of the undernourished child is to feed him as you feed a good horse or dog and I believe this to be the best preventive measure and therefore the best feeding method in childhood. Put the oats in the manger and let him take or leave them. No one would consider for a moment, sweetening a horse's oats with sugar in order to make him take them. At a recent "Better Food Demonstration" held by the State Teacher's College in Michigan a poster which apparently created some interest read "Use horse sense, eat oatmeal." More practical ad-

vice might be "Use horseman's sense, feed oats without sugar." A healthy appetite needs no tempting. Government through fear, as Judge Lindsay expresses it, produces the impulse to do the other thing.

My plea is for the appetite cure which Mark Twain has called "The Best and Wisest in the World." His advice was sound "Don't eat until you are hungry, if the food fails to taste good, fails to satisfy you, rejoice you, comfort you, don't you eat again until you are very hungry, then it will rejoice you and do you good too."

Criticism to be of value should be constructive. My suggestion for a scheme applicable to groups would be to consider all children undernourished, irrespective of weight or height, whose general appearance and attitude toward life do not give the impression of perfect health and comfort. Investigate home conditions and educate. Forced feeding and between meals luncheons have no place in such a scheme. If food is needed the place for its consumption is in the home and with the meals. Dietetic knowledge given to the laity should not be limited to the nutritive content of food stuffs, though I recognize fully the importance of such teaching. To be effective it must include an understandable portion of the physiology of digestion, stressing the point that assimilation is essential to nourishment. Supply more and better food to children in the home, at community expense if need be, but don't run the risk of ruining appetite and digestion by the school lunch. Most of those who get it don't need it and those who do don't need it when they get it.

Twenty-five years of experience with these problems has convinced me that what these children need is not more food but less, less effort to cause simple consumption of calories and vitamins, more sympathy for the digestive organs, less desire for size, more desire for health. In private work, I am sure, the elimination of between meals feeding, of tempting and coaxing, absolute ignoring of likes and dislikes will result in an appetite and digestion most efficient in the production of what we call health.

LADIN'S SIGN OF EARLY PREGNANCY—A POSITIVE SIGN OF PREGNANCY*

By DAVID W TOVEY, MD, F.A.C.S, NEW YORK

WHEN I first became a member of the staff of Brooks H Wells at the New York Polyclinic in 1903, he was teaching the students to diagnose pregnancy as early as the fifth and sixth weeks. He did this by Ladin's signs of pregnancy. Wells and Ladin had been associated on the staff of Paul Munde. Ladin discovered his sign working in Munde's clinic years before.

Vanderveer in 1887 (1) collected 75 abdominal sections by the world's greatest surgeons and gynecologists in which pregnancy was unsuspected. This shows the difficulty in diagnosing pregnancy at that time.

SIGNS OF PREGNANCY

The suppression of menses is of little value in the diagnosis of early pregnancy, as fear, chilling, anaemia, change of climate, early menopause will cause a cessation. Winfield Ney (2) has called attention to sexual infantilism, acromegaly in young women and tumors affecting the hypophysis cerebri as a cause of complete amenorrhoea. On the other hand uterine bleeding every month does not preclude pregnancy. In the first two months of pregnancy women often have a slight bloody discharge at the usual time of the menses which they speak of as menstruation, and pregnancy may occur during lactation.

VAGINAL SIGNS

Jacquenin's spot (3), a bluish spot two cm below the urethral meatus, on the anterior vaginal wall, is rarely present before the third month. So also the bluish color or blush of the cervix. Softening of the cervix, the sign most often spoken of, is rarely present before the third month. Changes in the cervix may prevent it entirely. The signs are unreliable.

FLEXIBILITY OF THE ISTHMUS-McDONALD'S SIGN

McDonald says, "to obtain his sign conditions must be ideal." It is important that no contraction of the uterus is occurring, as the uterus must be in a state of relaxation. (McDonald's *Journal of Obstet*, 1907). As the uterus is stimulated to contract by the examining fingers I have found it difficult to get this sign before the third month.

HEGAR'S SIGN (4), FIGURE 1

Softening and compressibility of the lower segment of the uterus is a valuable sign. This is not found before the ninth to twelfth week, as in the early weeks, five to eight, the uterus

is more contractile and irritable than later when the tissue is softer and the muscle flabbier. To get Hegar's signs it is necessary to press in the abdominal wall so that the uterine isthmus is between the abdominal and vaginal fingers. This is very difficult in young women and requires an expert in vaginal palpitation. Irregularity and asymmetrical enlargement of the uterus described by Dickerson (*Journal of Obstet* 1892) is the cause of errors in diagnosis, the pregnant uterus being mistaken for fibroids. This sign is not a help in the diagnosis of early pregnancy. One should remember that it occurs, to prevent mistakes in diagnosis.

FIG. 1—Hegar's Sign

THE JUG SIGN

This sign, in which the uterus is likened to the bulging part of a jug, the cervix to the sprout. To get this sign, see Figures 2 and 3.

Counter pressure is made above, fixing the uterus. With first and second fingers in lateral fornices, the lateral borders of the uterus are palpated. The normal uterus is pear-shaped and more or less triangular. The lateral borders gradually extend up to the uterine cornu. In pregnancy they are felt to be rounded and bulging like the sides of a jug, above the spout, the cervix. The change in the shape of the uterus, occurs early and when found is of value, in conjunction with Ladin's sign.

* Read before the Polyclinic Medical Society, December 7, 1925

LADIN'S SIGN (5)

An elastic area just above the internal os. It is well to remember that the uterus is often more flexed, in early pregnancy, due to the softening of the isthmus. The change described by Ladin is invariably found in early uterine pregnancy and is the only constant sign. It consists in a circular elastic area situated in the median line of the anterior surface of the body of the uterus just above the junction of the body and the cervix, that is to say, it is at the isthmus of the uterus which varies in size according to the duration of pregnancy and offers to the palpating finger the distinct sensation of fluctuation. It can be made out as early as the fifth week, when the area is the size of a finger tip and can always be felt in the sixth week when it is larger. As pregnancy advances the area increases in size in a crescentic manner and extends upward towards the fundus until the third month of pregnancy when nearly the entire anterior body of the uterus pre-

FIG. 2—Normal Uterus

sents a fluctuating cystic feel to the examining finger. The change in the consistency is observed on the anterior wall when the pregnant uterus is in the normal position or slightly anteverted, in retroverted or retroflexed uteri the elastic area is found on the posterior wall.

FIG. 3—Jug Sign

METHOD OF ELICITING LADIN'S SIGN FIGURES 4 AND 5

While the uterus is fixed by counter pressure by the external hand, the anterior wall of the uterus, from the cervix to the fundus is palpated by the vaginal fingers and if pregnancy exists the elastic fluctuating area will be felt in the median line of the body of the uterus immediately above the internal os. No special skill is required to recognize this elastic area. I am able to demonstrate it to students at the Polyclinic Hospital at the first examination. The sign is invariably present in early pregnancy, absence of this sign is an absolute indication for the exclusion of uterine pregnancy. Soft myoma or cystic fibroid, situated in the anterior wall of the uterus, is the only condition in which this sign is not diagnostic of pregnancy. Differential diagnosis is made in these cases by the uterus not enlarging.

DIFFERENTIAL DIAGNOSIS OF THREATENED, INEVITABLE AND COMPLETE ABORTION

In cases of early pregnancy with symptoms of threatened abortion, the area in the isthmus remains cystic and elastic so long as the ovum is viable, but become soft, doughy, and compressible as soon as the ovum is no longer viable—that is to say in incomplete abortion. Furthermore in sub-involution following abortion a change in the consistency of a similar area is also manifest. Here again the feel is soft and doughy instead of the elastic cystic feel of pregnancy or threatened abortion.

FIG 4—Ladin's Sign, Lateral

DIFFERENTIAL DIAGNOSIS IN UTERINE AND EXTRA-UTERINE PREGNANCY

The one condition from which ectopic pregnancy must most frequently be differentiated is uterine pregnancy. Confirming a diagnosis of uterine pregnancy will at once preclude the possible presence of ectopic gestation and vice versa. The absence of uterine pregnancy will presume the presence of ectopic pregnancy. Ladin's sign is due to a hypertrophy involving the muscular fibers, connective tissue, and especially the vascular lymphatic structures of the uterus. These changes take place in the whole uterus but are most marked and occur earliest in the isthmus. Care should be taken in eliciting Ladin's signs to wait until the contractions of the uterus caused by stimulation of the examining fingers have ceased. I believe in cases in which we are not able to get the sign on first examination, there is intense contractions of the uterus caused by the examining finger. When the patient comes for the next examination the sign is easily found. When I first was testing the sign in the old Polyclinic I examined a very young woman Brooks Wells came into the room just as I finished. I said, "Wells, this girl thinks she may be pregnant, but she is not." Wells examined her and said, "Examine her again, Tovey, she is about six weeks pregnant." The area that felt hard to me a few minutes before was cystic and elastic. My fingers on first examination had stimulated a contraction of the uterus. Some years ago a sister of a prominent

member of the Polyclinic staff was taken, after skipping four weeks, with spotting and severe pain in the right ovarian region accompanied by faintness. As she was to go to the country in a day or so it was necessary to rule out ectopic pregnancy. Examination showed the uterus to be slightly enlarged but Ladin's sign could not be felt. She was very tender in the right ovarian region and very nervous. Examination under ether, Ladin's sign was easily felt, a diagnosis of pregnancy was made and the patient went to the country. Contractions of the uterus in a neurotic woman prevented getting the sign at the first examination.

Corpus luteum cysts are frequently mistaken for ectopic pregnancy. The symptoms of corpus luteum cysts are almost identical with ectopic and at times it is difficult to differentiate.

In one case I made a diagnosis of corpus luteum cyst but told the woman she might have

FIG 5—Ladin's Sign, Anterior

an ectopic. She was a single girl. I operated and found an unruptured ectopic with a small nodule in the tube about the size of a pea. Dr. Losee examined it and found it to contain blood clot and chorionic villi.

INFLUENZAL CROUP*

By EDWARD L BENJAMIN, M.D., NEW YORK

DURING the past winter while influenza was rampant, I had occasion to observe a number of cases of influenzal croup, and I've selected three such cases that demonstrate, more or less definitely, the course in almost all of them

There is no doubt that influenzal croup is an entity and that it is characterized by definite symptoms and a definite clinical course. All the cases observed and especially those reported here, gave a history of exposure to gripe, followed by the symptoms of laryngeal stenosis of croup after several days' illness.

The first case was that of a child four years of age with no previous illness. The onset was sudden with fever, general malaise and cough. Examination of this child revealed a naso-pharyngitis and bronchitis with a slight congestion of both ears.

On the fourth day of the illness the child suddenly developed dyspnoea which was slight at first. After a few hours this dyspnoea increased in intensity until marked retraction of the upper and lower chest, stertorous breathing, cyanosis of the face and profuse sweating developed. The child presented the typical picture of one with a laryngeal stenosis of croup. These attacks continued irregularly for two days, the actual spasms lasting from two to ten minutes and often accompanied by absence of any pulse. The child received thirty thousand units of diphtheria antitoxin during this siege on the supposition that I was dealing with a case of laryngeal diphtheria. Repeated cultures of the nose and throat were negative for diphtheria, but showed mostly B. Influenza with few Pneumococci and M. Catarrhalis.

The spasms of laryngeal obstruction lasted two days, during which time the temperature ranged from 101° to 103.4°. The child did not improve or show any reaction following the administration of diphtheria antitoxin, but responded wonderfully well to full doses of morphine and atropine and steam inhalations of cod. benzoin with spt of camphor and eucalyptol and adrenalin (1 to 1000). Examination of chest revealed the presence of many dry rales all over the chest with a preponderance of sibilant and sonorous rales. Tonsils and larynx were free of any membrane, but the mucus membrane of the mouth and throat showed a peculiar red and dry appearance as opposed to the moist appearance of the mucus membrane in true diphtheritic croup. This child was quite exhausted following these at-

tacks and after stimulation for several days fully recovered.

The second case was that of a child nine years of age, whose history showed that it had had frequent attacks of bronchitis. No other illness. This child was taken ill suddenly with nausea, vomiting, headache, fever and cough. The temperature ranged from 101.6° to 103° for eight days before the onset of the symptoms of laryngeal stenosis. On the eighth day of the illness he suddenly developed dyspnoea, which became more severe as it progressed. On the eleventh day of his illness, the picture was complete—the dyspnoea had developed rapidly into that of one in laryngeal spasm of croup, with the accompanying cyanosis, loud breathing and retraction of the chest. During one of his spasms he became so cyanosed that I was ready to do a tracheotomy. But fortunately the morphine and atropine and adrenalin along with the steam inhalations controlled the attack.

These spasms continued for five days, when they gradually became less intense and disappeared entirely. In this case also nose and throat cultures repeatedly were negative for diphtheria, but showed the presence of B. Influenza.

This child also received thirty thousand units of diphtheria antitoxin, but it was quite apparent that he did not respond to this—i.e., as far as the spasms were concerned—but definitely responded to the morphine and atropine injections.

The case was complicated further with an otitis media for about a week, after which the child fully recovered.

The third case was that of a child, six years of age, with a past history of measles, pneumonia, pertussis and diphtheria. Onset was similar to that of the other two cases—the child was ill for three days with headache, cough, general malaise and pains in limbs—with the spasms occurring on the third day and continuing for two days.

The spasms of laryngeal obstruction in this case were not so severe but appeared to be to the mother—since she swooned with nearly every attack the child had. On the fifth day of his illness, while the intensity of the spasms were gradually decreasing, this child had a severe nose bleed which lasted several hours. Repeated cultures of nose and throat of this case up to the twelfth day of his illness were negative for diphtheria. Twenty thousand units of antitoxin were injected as a precautionary measure, however. The child recovered and showed no ill effects as the result of the spasms.

* Read before the Lebanon Hospital Alumni Association
March 1926

It is to be noted that in all of the cases the onset was the same—the clinical course of influenza for a few days, followed by the appearance of the symptoms of croup. In the first two cases, the spleen and liver were palpable until the end of the illness. A blood examination in the first case showed RBC = 4,145,000 WBC = 5,500 (leukopenia), P 86, L 14 and Hgb 65 per cent.

CONCLUSION

1 Owing to the difficulty in making an immediate and definite differential diagnosis from laryngeal diphtheria or true croup, it is best to administer diphtheria antitoxin first and question the cultures afterwards.

2 These cases did not show any membrane at any time.

3 Antitoxin while administered early and in sufficient quantities did not have any effect on the spasms.

4 Injections of adrenalin (1 to 1000) morphine and atropine and the steam inhalations seemed to affect the spasms definitely and reduce the oedema causing them.

5 The condition—influenzal croup—is well defined and is more common than we suspect during an epidemic of influenza.

6 The prognosis is generally good if treatment is instituted early and properly and no complications occur.

THE SIGNIFICANCE OF HEMATURIA

By A STRACHSTEIN, M.D., NEW YORK

IT cannot be emphasized too frequently nor too emphatically that the fate of the individual affected with hematuria largely depends upon an early diagnosis of his condition. Unfortunately, this is not universally recognized for, practitioners are still met with who deal with hematuria as an inconsequential symptom, thus losing valuable time which frequently not only jeopardizes vital organs, but also the very life of the patient.

In reviewing a series of cases in which hematuria was the dominant symptom, our observations concur with those of others (1) who state that hematuria should be looked upon as a symptom of serious import. While in a large number of cases hematuria was found to be due to malignant disease, in a number of other instances it has indicated the presence of a condition which, while not malignant, would probably lead to the ultimate destruction of the organ involved, and in some instances to the loss of the life of the patient as well.

Hematuria, with very few exceptions, means the presence of organic disease in the urinary tract, and its importance should not be underestimated or belittled. (2) Because of its frequently painless nature, the patient is often treated for months, and in some instances for years, without seeking the aid of the urologist who could in most cases, determine the cause, thereby making it possible to apply timely and proper remedial agencies.

The most frequent type of unrecognized hematuria is that observed in young adults suffering from renal tuberculosis. In this group, failure of an early diagnosis leads to not only destruction of the primary involved kidney, but

eventually to extensive vesical involvement and to an ascending infection of the opposite kidney, which could otherwise be saved.

It is very generally accepted that renal tuberculosis is unilateral in the earlier stages. It subsequently becomes bilateral when considerable time is allowed to elapse after the appearance of the first warnings. Kronlein (3) states that 92 per cent and Legueu (4) 85 per cent of the cases are unilateral. On the other hand, cases that are allowed to go on for some time unrecognized, eventually become bilateral.

The following two cases will illustrate how a timely and proper examination would have entirely altered the chances for a complete recovery.

CASE 1—N. C. male, age 19, came under my observation in 1924.

Previous history negative except for polymyositis in childhood.

Present history. One year ago, he insidiously developed frequency of urination which very gradually grew progressively worse. He soon began to notice bloody urine, and ten months ago he had a severe attack of hematuria. Ever since then, his urine was never entirely free from blood. Was treated until now with bladder irrigations.

Cystoscopic Examination. Bladder urine appears pale, cloudy and admixed with blood. Bladder is extremely sensitive and shows a diffuse cystitis, especially along the left ureter orifice.

Ureteral catheterized specimens of urine show pus and tubercle bacilli from left side, and a moderate amount of pus but no tubercle bacilli microscopically from the right side.

Guinea-pig injections reveals the presence of tubercle bacilli in the specimen from the right side as well.

CASE 2—J P male, age 33

Previous history Spinal meningitis in childhood

Present history Eighteen months ago developed gradual frequency of urination which slowly grew progressively worse. A few weeks after onset of frequency he noticed bloody urine and frequently passed blood clots. Ever since then, the hematuria was of frequent occurrence. Treated until recently for cystitis.

Cystoscopic examination without anesthesia at the present time is impossible, owing to the extreme irritability of the bladder. A voided specimen of urine shows much pus, blood, and loaded with tubercle bacilli.

No comments are necessary as to what an early urological examination would have done for these two patients.

The next important group is the one in which the hematuria is due to a vesicle tumor. There are many competent pathologists who hold that all bladder tumors either are malignant, or eventually become so.

Of course, clinically we have all had cases of vesical pedunculated papillomatous growths that disappear under Beer's fulguration. The absence of their reappearance is perhaps largely due to the early recognition and treatment. Here too, one can readily conceive of the harm done by the neglect or delay of an early diagnosis. The harm

lies not only in the failure of an early diagnosis, but also in the fact that ultimate extensive involvement makes it impractical to resort to fulguration since a proper application of this method would again consume several weeks of time which the patient at this late hour, can ill afford to lose. Yet cases of this sort are met with that are being treated for nephritis, although it is admitted that nephritis occasionally is a sole cause for hematuria.

Still another common group of cases are the quiescent renal calculi. Frequently recurring hematuria may be the dominant symptom. Failure of an early recognition tends to calculous pyonephrosis with ultimate complete loss of function of the involved kidney.

Of course, it is not intended in this paper to deal with the very many possible causes of hematuria. The real purpose is to sound a word of warning that the more common cases of persistent hematuria is of serious import and should not be dealt with lightly. An early urologic examination and diagnosis will very frequently mean saving of the patient's life, if not the affected organ.

MAXILLARY AND SPHENOIDAL SINUSITIS IN CHILDREN*

By WILLIAM ANDREW KRIEGER, M.D., F.A.C.S., POUGHKEEPSIE, N. Y.

IT is the firm belief of many investigators that certain constitutional disorders have been caused by suppurative disease of the paranasal sinuses. Some of these constitutional disorders can often be traced to childhood when sinus disease began.

It is quite impossible to deal with maxillary and sphenoidal sinusitis without a consideration of the ethmoidal and frontal sinuses, neither is it possible to deal with these two sinuses exhaustively, as time would not permit and most of the important features have been covered by men who are authorities on these subjects. I therefore, shall confine myself in this paper, to the presentation of a few facts of diagnosis and treatment in the ambulatory and semi-ambulatory cases that have occurred in my private practice. The late cases requiring major surgery will not be considered.

The anatomy and development of these sinuses and the neighboring structures must be constantly kept in mind. The fact that the maxillary sinus and the development of the nasal wall can not be considered in the adult

stage until after the fifteenth year is of great importance. According to Schaeffer, the sphenoid becomes the primitive sphenoidal sinus during the fourth year, and previously, that is, up to the end of the third year the rudiment of the sphenoidal sinus is surrounded by bone, except ventrally toward the nasal fossa, where an opening exists. The mucosa of the sinuses is directly continuous with that of the nasal fossa. Owing to the looseness of the tissue about the ostia of the sinuses, the mucosa is especially prone to swelling and thickening. The lymphatics are also directly connected with those of the nasal mucosa.

Infection of the maxillary and sphenoidal sinuses is much more frequent than is commonly believed by many internists and pediatricians. In children, many cases of acute illness with headache, fever, loss of appetite and vomiting, and in some cases leucocytosis, are found to be suppurative sinus disease, when examined carefully. Then there is the group of cases that are apparently well. The parents give a history of the child having an upset stomach and feverish one day and normal the next few days, with a recurrence of these

* Read at the Annual Meeting of the Medical Society of the State of New York, at New York, March 31, 1926.

It is to be noted that in all of the cases the onset was the same—the clinical course of influenza for a few days, followed by the appearance of the symptoms of croup. In the first two cases, the spleen and liver were palpable until the end of the illness. THE DISTRICT BRANCH MEETINGS

The attention of the members of the Medical Society of the State of New York is called to the meetings of the District Branches, a list of which was published in this Journal on August first. The program of the Third District Branch is printed on page 762 of this Journal, and those of the other districts will be published as soon as they are received.

Plans are made for reporting the meetings in this Journal promptly.

The District Branch meetings will afford the opportunity for the county officers to meet the representatives of the Journal and give them the news and impressions from their home societies. One great object of this Journal is to provide a medium for the dissemination of news regarding the county societies. The officers of the county societies are expected to attend the District meetings, and both bring and take away medical news of mutual helpfulness.

symptoms at intervals. Or they may consult you to see whether the child has a return of adenoids because there seems to be a recurrence of cough and difficult breathing, a condition similar to that before the adenoids were removed. These cases on careful examination, after shrinking the nasal mucosa thoroughly, will almost invariably show discharge posteriorly from the sphenoid area and also from the middle fossa. If no discharge presents itself, it can frequently be obtained by the application of a small suction tip to the sphenoid area and the middle fossa.

In the diagnosis of sphenoidal sinusitis, the ophthalmoscope, to my mind, is invaluable. In the vast majority of my cases, I have found a definite edema over the superior nasal quadrant of the optic disc and frequently some edema of the entire disc. The amount of edema apparently has a definite relation to the amount of sphenoidal drainage. This is a very important diagnostic sign, especially so where it is almost impossible to make a careful nasal examination of the child. It is also an excellent guide to the progress of the disease, as it is interesting to see this edema disappear as soon as adequate drainage is established. If the symptom is watched carefully and proper treatment instituted there is no loss of vision, but if these cases are unrecognized and an optic neuritis occurs, of course, there is a very definite diminution of vision. Although X-ray has an important place in the diagnosis of sinus conditions, it is hardly necessary to discuss it in this paper.

Arbuckle states that in the St. Louis Children's Hospital and in private practice he has well authenticated cases of cardiac disease, nephritis, arthritis, bronchitis, erysipelas and psychoneurosis in which the cause apparently was suppurative disease of the paranasal sinuses. He further alludes to Birk's description of Czerny's exudative diathesis as remarkably similar to that of the condition found in infants who have suppurative disease in the nasal sinuses. Chorea with heart involvement has frequently been successfully combatted by treating an existing paranasal sinus infection. Herpes zoster over the first division of the fifth nerve has been found by Arbuckle to accompany acute suppurative disease of the sphenoid. Arbuckle quotes Marriot as stating that one of the most frequent and most serious of the systemic manifestations of sinus disease in children is acute parenchymatous nephritis.

According to Dean, phlyctenular conjunctivitis, iritis, retrobulbar neuritis and choroiditis are frequently very definitely associated with sinus infection. He also calls attention to a very possible relation between chronic multiple infectious arthritis and paranasal sinus

disease in infants and young children, also to the fact that the absorption of bacterial protein from an infection of the sinus may be an etiological factor in the causation of asthma in children, a theory advanced by Byfield and others. Dean further states "that any condition in infants and young children that may result from a focus of infection may be caused by sinus disease and that chronic sinus infections produce listlessness, poor color, underweight, poor appetite and certain cases of cyclic vomiting, in other words, the conditions which are commonly supposed to be due to tonsils and adenoids."

The fact that we are dealing with a mucous membrane which is to have a highly specialized function throughout the life of the individual, must never fail our consideration. In order to prevent the more radical operations we must see these cases early and have the complete co-operation of the pediatrician and internist. Most of the pathogenic bacteria found in the nose produce an acid reaction when grown on artificial media, they also have this tendency when growing in the nose. When this acidity becomes excessive it devitalizes the tissues and renders them more susceptible to secondary infection and toxic absorption. In my cases, I have had the most satisfactory results with thorough cleansing of the nasal cavities followed by alkaline solutions of varying strength, rather than with strong antiseptics or solutions that in any way irritate the mucosa. The suction is of great importance as it can be applied without a general anæsthetic and in most cases the sphenoid ostium can be reached with a flexible curved tip. Sufficient discharge can be removed to relieve pressure and establish drainage with little, if any danger to the patient. Owing to the formation of the nasal wall, the maxillary sinus can be reached and treated in a similar way without danger to the teeth or to the orbit. After the nasal cavities and sinuses have been cleansed as thoroughly as possible, I have found the Kromayer lamp an invaluable adjunct. With the variation of tips the light can be applied to any nasal cavity. It is not painful and after one or two applications the child rather enjoys it. In my cases it has produced a very definite beneficial effect, apparently having a marked bacteriacidal action where the rays come in contact with the bacteria.

In conclusion, let me impress upon you the ophthalmoscope and suction as a means to diagnosis, the suction, alkalinization and Kromayer lamp as treatment. The interdependence of the eye and the nose is too often overlooked or discounted as a secondary consideration. But let me say that to consider one without the other is to make but half a diagnosis.

LITERATURE ON THE COUNTY MEDICAL SOCIETY

There is only a meager amount of literature on the subject of the County Medical Society. The State Medical Journals are almost the only repositories of literature concerning the county societies. State societies have their journals. The A M A has one of the greatest medical journals in the world, and the societies of specialists publish their own organs, but the fundamental society of them all—the County Medical Society—receives little attention in literature.

Most state journals try to publish the proceedings of their County Medical Societies, but the literature can hardly be called inspiring. THE NEW YORK STATE JOURNAL OF MEDICINE publishes reports of the meetings of only about one-half of the societies—the proceedings of the others, equally good perhaps, or better remain unknown except to those who attend them, and this faithful group has no means of preserving their record for future reference.

Besides the records of the meetings printed in the state journals, almost the only other record is that contained in footnotes appended to scientific papers stating that they were read before a County Medical Society, and only a small minority of papers are so labelled, for the most of them are read before other societies.

Why does the County Society not receive more recognition in medical literature? One reason is that the local leaders do not send

the news about their societies. The state journals offer their space, and only half the societies accept it. Space in a state journal has a value which the County Societies have been slow to capitalize.

The leaders of State Societies may sometimes fail to bring their journals to the attention of the county societies, and the members of the local societies then fail to realize the value of the publicity. It pays the State Medical Society to advertise the advantages that will accrue to the County Society through publicity of its proceedings.

THE NEW YORK STATE JOURNAL OF MEDICINE urges the leaders of the County Societies to set a higher standard in the amount and quality of the literature regarding their organizations. Every assistance will be given to the writers to make their reports worthy of permanent preservation.

A problem which confronts the Secretaries' Association of New York State is the standardization of methods and activities. The first step in that unification is the collection of records of what the County Societies are doing. The State Journal should be the natural source of that information. Surely, there is in every society some member who is willing to send the news of his society to the Journal. The New Jersey plan of having a reporter in each society is worthy of trial in New York State.

LOOKING BACKWARD

THIS JOURNAL TWENTY-FIVE YEARS AGO

Bovine Tuberculosis—Twenty-five years ago physicians disagreed regarding the relation of bovine tuberculosis to the human type of the disease. Professor Koch argued that man could not be infected with the bovine germs. He seems to have found adult persons immune to infection with the germs of bovine tuberculosis, but it is now well known that children may be infected readily.

This Journal of September, 1901, contains the following editorial on the subject:

"Prof. Koch on Tuberculosis—One of the most encouraging signs of the times is the widespread interest in medical topics among the laity as indicated by the amount of space devoted to them in the public press, and the increasing accuracy of the reports. Under such circumstances the recent declarations of Koch, at the British Congress on Tuberculosis, excited widespread interest. Briefly, his opinions, based on a rather short course of experiment, are these: That bovine tuberculosis and human tuberculosis are radically different diseases, and that cattle cannot be infected from

human beings. Of the converse, that human beings cannot be infected from animals, he could of course produce no experimental proof but he declared himself convinced, and cited in support of his conclusions a good many facts of common observation. Of course, if these views are correct, all the money spent by the public to restrict the spread of animal tuberculosis has been largely wasted. It is a pity that a man whose opinion carries such public weight should make such definite statements without a far greater amount of experimental proof, and we are glad to see that this was the position taken by the conservative judgment of the congress. The proof of a negative proposition should always be subject to careful scrutiny. At the same time, we think that only good can come from the widespread publication of the fact so reiterated at the congress, that consumption is chiefly propagated through the sputum. We can also enjoy the many complimentary notices by Koch and others of the great advances made in this country in the public control of tuberculosis."

OPPORTUNITIES OF THE DISTRICT BRANCHES

The three or four weeks beginning with the middle of September is the time when most of the District Branches of the Medical Society of New York State hold their annual meetings. The District Branches are laid out along geographic lines so as to enable the members to get together readily and discuss their common problems.

The importance of a District Branch is not to be measured by the size of its membership, whose numbers vary between 4,500 as a maximum and 450 as a minimum. But the smallest Branch is large enough to carry on a wide line of activities, and as a matter of fact the attendance at its meetings has been much above the average of the others.

A District Branch has a triple function. It holds an annual meeting, and it elects a member of the Council of the State Medical Society. The third function of the District Branch is that of an intermediary between the State Society and the county societies. The leaders of the District Branches expound the policies and activities of the State Society to the local societies, and likewise, they bring to the State Society intimate information regarding the local societies and the practice of medicine in the counties. Every District Branch has a group of men who are towers of strength to the medical profession and to the public. These men are known throughout their districts, and the fame of many extends to the State and the Nation. Excellent personnel for leadership is available in every Branch.

The duties of the District Branch leaders to the State Society are well performed. The Councilors and committeemen attend their meetings faithfully, and show a commendable knowledge of local conditions. The State Society is fortunate in its method of local representation and the character of the representatives.

The relation of the District Branch to the county medical societies is balanced against its relation to the State Society. The State Society is now symmetrically formed and effectively administered, and the next great item of progress will be to bring the county societies up to its own standard. Progress always begins in a one-sided way. Some individual or society sets a new standard, and the others seek to emulate it. Every county society does something much better than any of its neighbors, and its members go along their plodding ways unaware that they have done a commendable piece of work which is worthy of imitation by other county societies.

The great difficulty with county societies,

as with rural health boards, is that they do not apply standards of measurement to their work. A great health department, or a county society including a big city, will keep a record of the small items of its activity and make an impressive showing in an annual report. The secretary of a small county society hoards the record of similar items in his mind, and neither uses them himself nor gives them out to others. He is not conscious of a neglect of opportunities, because no one has ever made use of the items, or asked him to keep them, or commended him when he has done a good piece of work.

It is the intimate contact with the county societies that offers the District Branch its greatest opportunity of usefulness and progress. The By-Laws of the State Society, Section 41, provide that "Each district councilor shall visit the counties of his district at least once a year and make a careful inquiry of the condition of the profession in each county in his district, and shall report thereon to the House of Delegates." But the By-Laws are silent regarding the further duties of the councilors and other District Branch officers to the county societies.

A balanced program of progress requires the county societies to progress equally with the State Society. The District Branches are naturally fitted to lead in that progress, and to stimulate the counties to activities along practical lines. If one county does anything well, let the councilor use its example as a stimulus to the other counties in his district. If an ideal county society were to be organized, on paper, most of its features could well be those which are found in operation in some society of almost any District Branch. What is needed is not so much new ideas or new organizations as the record of the ideals, aims, and accomplishments that are already in evidence in some society in every District Branch—one item in this society and another in another.

The leaders of the District Branches have the opportunity to inspire the local societies to develop those other activities that are promoted by the State Society, but they may go further and show the State Society new fields of activity.

The county societies and the State Society are receiving full recognition. The time has come for the District Branches to assert themselves so that they shall receive the recognition that is commensurate with their opportunities and importance.

Laxatives and Purgatives—Factors upon which regular and efficient action of the bowels depend are, according to Charles W Chapman (*Practitioner*, May, 1926, cævi, 5), early and persistent training from the nursery period to adolescence. This includes training to heed the call of nature, food appropriate to the age and constitution of the child (avoiding particularly chocolate and other sweets at odd times), thorough mastication of food, and walking exercise at all ages. In older persons with either constipation or diarrhea the possibility of malignant disease should always be borne in mind. It should also be remembered that it is possible to have a persistent diarrhea and at the same time a rectum loaded with scybala. The habitual use of strong purgatives clears away good material along with the useless, to the lowering of general nutrition. Salines, such as the sulphates of sodium and magnesium, though useful at times, are not applicable where masses of scybala are present, since they are prone to cause only watery motions while the lumps may be left undisturbed. Laxatives are not open to these objections. The most reliable laxative is senna, alone or in combination with tartrate of sodium and carminatives. A formula in frequent use at the Royal General Dispensary during the writer's pupilage there was confection of black pepper (B P), $\frac{1}{2}$ ounce, confection of sulphur, 1 ounce, confection of senna sufficient to make 3 ounces, one or two teaspoonfuls to be taken each night. After a first copious action, only sufficient to produce one easy evacuation daily should be taken. Cascara, with or without small doses of extracts of *nux vomica* and belladonna, makes a useful pill in obstinate cases. Castor oil and petroleum are useful laxatives.

Method of Treating Asthma by Radiation —

In a preliminary report, S Gilbert Scott (*British Medical Journal*, June 5, 1926, 3413) relates that while treating patients who had been operated upon for carcinoma of the breast, with the γ -rays in the endeavor to prevent metastases, he observed that those suffering from bronchitis appeared to be relieved by the treatment, and one woman who had asthma for fifteen years claimed to have been cured. This aroused his interest in the subject, and during two and a half years he has treated with γ -rays 21 cases of chronic asthma of various types with relief of symptoms in every instance, though the number of treatments given to get rid of the wheezing varied. The immediate effects are experienced within a few hours after the treatment. There follows improvement in the patient's general condition, and in most cases a definite increase in weight. The original dose given was the same as that for carcinoma, but it was found that 10 X, through 3 mm of aluminum gave as good results in asthma, and did not cause any general disturbance. The field of radiation should be large, including practically the whole trunk,

as radiation of the thorax alone does not give the results. Because of the large area radiated a low voltage is desirable. The use of two tubes, one in front and one in the back, saves time. The 10 X dose is administered once a week in the average case, and twice a week in severe cases. After the fourth dose an interval of two weeks is allowed. The treatment is repeated once a month for four months.

Diathermy in the Treatment of Multiple Sclerosis—Junius W Stephenson, writing in *Physical Therapeutics* for June, 1926, reports two cases of multiple sclerosis in the treatment of which diathermy was employed with very satisfactory results. The first case was that of a young woman of 25 years who first noticed "numbness and weakness" in her legs and "pins and needles" sensation in the fingers in May, 1922. This condition persisted for about six weeks and then disappeared. A year later she was suddenly seized with a second attack, with similar symptoms, which lasted six or eight weeks. At the end of another twelve months (June 1924) a third attack appeared, marked by weakness in the legs and coldness with "pins and needles" in the hands. The weakness in the legs was recovered from, but the paresthesia in the fingers persisted up to the time Stephenson saw her in August, 1925. About two months before this a fourth attack came on and was not recovered from when the writer examined her. At this time there was astasia with the eyes closed, the gait was markedly ataxic, there was inconstant nystagmus, the deep reflexes were exaggerated, but neither the abdominal nor the epigastric reflex could be elicited. The sense of position was preserved in the left toes but lost in the right. The Babinski, Gordon, Oppenheim, and other reflexes were present on both sides but more marked on the right. The sensory findings pointed to lesions in the upper dorsal and lower cervical regions, and accordingly the diathermy pad, 5 inches long and $2\frac{1}{2}$ inches wide, was applied from the 7th cervical vertebra down. The dosage was 500 ma, gradually increased to 1400 ma for 20 minutes three times a week. Improvement was apparent almost from the first, and five months after the first treatment locomotion was normal and there was merely a suggestion of swaying with the eyes closed. The patient could walk in a straight line and the finger-nose and knee-ankle tests were perfect. In the second case the symptoms dated back 18 years, but the improvement following diathermy was prompt and marked. Unfortunately the patient has disappeared, so that it has been impossible to follow up the case. Of course in a condition characterized by remissions no definite conclusions can be drawn from the results in these two cases, yet the prompt improvement in the sensory symptoms and the concomitant changes in the pyramidal findings afford a presumption of therapeutic efficacy in the diathermy, and warrant further trials of it.

MEDICAL PROGRESS

The Significance and Treatment of Hemorrhages—Writing on this subject in the *American Journal of the Medical Sciences* for July, 1926, clxxii, 1, C A Mills classifies bleeding under three heads (1) Hemorrhage from physical causes, such as trauma, either accidental or surgical, congestion and venous rupture, arteriosclerosis and hypertension (2) Hemorrhages as a feature of other diseases, such as subacute or chronic infection, malignant fevers, anemias, leucemia, jaundice, metabolic disturbances, and tumors, particularly carcinoma (3) Hemorrhages in the truly hemorrhagic diseases, such as hemophilia, purpura, and melena neonatorum

The characteristic feature of the types of bleeding in the first group is that the trouble lies in the physical forces and not in the blood itself. In the second group, on the other hand, the trouble lies in the blood which has been chemically altered as a result of infection, malnutrition, anemia, or jaundice, there being an excess production of antithrombin, there may, indeed, be some tissue destruction as well, but the main factor is the blood change. In the third group also the trouble lies in the blood itself, but in this case it is as it were idiopathic and independent of any other pathological condition in the patient. In hemophilia the abnormality occurs wholly in the thrombin-producing and thrombin-destroying mechanism, the blood fibrinogen and calcium content being normal. True purpura seems to be entirely dependent on the abnormal character of the blood and more particularly of the platelets which are reduced in number. The source of the trouble, at least one source, has been thought to lie in the spleen where a too active platelet destruction occurs. Melena neonatorum, the author thinks, may be explained by the physiological fact that all infants exhibit a lengthening of their clotting time from about the third to the seventh or eighth day of life, this change being very marked in some, who may then develop a dangerous hemorrhagic condition.

In the treatment of internal bleeding we are passing beyond the stage of absolute quiet, ice-bags, bandaging of the limbs, etc., and are learning more effective measures. Today transfusion is recognized as one of the most certain means of arresting hemorrhage of whatever kind, but owing to its technical difficulties it is necessarily a measure of last resort. A further advance in the control of external bleeding is the use of tissue extracts, such as cephalin and lung saline extract, but the fear that strong coagulants given internally would cause intravascular clotting has prevented their use in bleeding from inaccessible regions. The author has however succeeded in isolating the active coagulant from those tissue extracts so that

it may be used internally without fear of the toxic action of the crude extracts. This coagulant, "tissue fibrinogen," may be used internally with safety, rapidly controlling bleeding whether internal or external. Given subcutaneously it begins to exert its effect in from sixty to ninety minutes, but when given by the mouth when the stomach is empty, followed by a glass of ice-water, its maximum effect is observed within fifteen minutes. The duration of the effect is about eight hours following subcutaneous injection, and from four to five hours following oral administration. It should never be given intravenously because of the intravascular clotting which would then inevitably follow. This tissue fibrinogen will control practically all the hemorrhages of the first group and most of those of the second. Some of the second group, however, call for quite other treatment, such being especially the hemorrhagic states in severe and rapidly progressive secondary anemia and in jaundice. In these cases transfusion is the most reliable measure, as it is also in hemophilia, though the latter occasionally responds to treatment by tissue coagulant. The author mentions in this connection the curious discovery by Vines that the induction of an anaphylactic state by sensitizing the patient through the injection of 4 c.c. of sheep or hen serum and after a week or ten days injecting a few drops of the same intradermally will arrest the bleeding of a hemophiliac and cause the clotting time to remain quite normal for several weeks. Melena neonatorum should be treated by transfusion of the mother's whole blood into the superior longitudinal sinus of the infant.

In concluding his paper Mills refers to the many cases in which recovery from disease has followed promptly upon the occurrence of spontaneous hemorrhage. During the influenza epidemic of 1918, he says, it was noticed in some of the camps that the soldiers who contracted influenza and had an early hemorrhage recovered most quickly from the disease. This led to a trial of therapeutic bleeding early in the attack with very good results in shortening its course and severity. In typhoid fever also it has been noticed in Cincinnati that when patients who had intestinal bleeding, which was arrested by tissue fibrinogen, usually recovered almost by crisis immediately following the hemorrhage. He suggests that there is some close connection between spontaneous bleeding and the cure of disease through stimulation of the immune mechanism, and says that what we particularly need is some way of estimating this curative or immunity-stimulating effect of bleeding, so that we may give venesection an intelligent trial, and perhaps return to the practice in suitable cases.

patient grows older, or may become more and more serious and finally prove fatal (2) The development of telangiectasæ, sometimes as dilated capillaries, sometimes as a network of dilated venules, more characteristically as spider nevi, occurring sometimes in youth, more often in adolescence or adult life, and usually increasing with the passing years (3) The occurrence of these symptoms in several members of the family Usually the same individual presents both groups of symptoms, but sometimes one group or the other may be missing in an individual case Williams says that, while this disease has hitherto been regarded as one of great rarity, his experience leads him to look upon it as exceedingly common He thinks its frequency would soon be established if every physician seeing a spider nevus would ask about the occurrence of nose-bleed in the patient and in other members of the family

Influence of Insulin in Cancer—V R Stuhler refers to the work of Warburg in showing that the cancer cell splits sugar with formation of lactic acid and to his generalization that there can be no growth without glycolysis Insulin has been administered in various forms of experimental cancer and apparently always with inhibition of cancer growth Given in advance of implantation it shows the same inhibitory action It will be remembered that if sugar and adrenalin are simultaneously injected cancer growth is stimulated The author tested insulin injections in 14 patients with inoperable cancer, mostly recurrent The remedy was pushed by giving relatively small doses daily for several weeks In 12 of these cases no inhibitory action was shown, but in the other two such action was present in a remarkable degree The cancers in these cases were situated on the face and while very destructive could hardly be compared in severity with cancer of the cervix and breast Cancer is now generally held to produce (or is it, to result from) a disturbance in the carbohydrate metabolism, and in nearly all cases, if not all, there is an increase, however slight, in the blood sugar Any general remedy which will antagonize cancer will, the writer believes, probably reduce the percentage of blood sugar This was evident in the two cases benefited by insulin but naturally it is the function of insulin to reduce blood sugar in all individuals treated Judging from the two cases the patient, to benefit by insulin, ought to be undernourished, for in these cases the remedy caused the patients to take on a few pounds of weight—*Wiener klinische Wochenschrift*, June 17, 1926

Loss of Weight as an Early Symptom in General Paralysis—In the course of a study of

74 cases of general paralysis of the insane, made with a view to determine the primary symptoms of this condition, Henry A Bunker says that he was impressed by the relative frequency with which loss of weight was mentioned among the early symptoms of the condition Thirty-eight of these seventy-four patients suffered from loss of weight at some time subsequent to the earliest signs of the onset of the paralysis, but prior to the necessity for their commitment, and of these thirty-eight, the loss of weight was essentially the earliest abnormality noted in twenty-two In twelve of the thirty-eight patients there was also a history of bulimia developing some time after the commencement of the loss of weight which in a few cases was successful in counterbalancing that loss to a considerable extent The author suggests the possibility of a relationship of these findings to the therapeutic response of the patients, since the greater number of those who regained their weight by the increased food intake responded very favorably to treatment, while four in whom treatment was of no avail had bulimia but did not thereby regain their weight—*Archives of Neurology and Psychiatry*, July, 1926, vi, 1

Irradiated Orange Juice—As experience in the use of ultraviolet light grows apace it is found to possess many virtues and powers which were unsuspected in the beginning Not the least interesting of these discoveries is the power of these rays to impart antirachitic properties to substances not previously capable of preventing or curing rickets Among the substances which can acquire antirachitic efficacy through exposure to ultraviolet light is milk In searching for an agent which would be at once antiscorbutic and antirachitic H L Maslow, D H Shelling, and B Kramer (*Bulletin of the Johns Hopkins Hospital*, cxix, 1, July, 1926) experimented with rayed orange juice They employed a concentrated orange juice, one part in two parts of distilled water, irradiated for three hours under a mercury vapor quartz lamp at a distance of 18 inches This was fed to rachitic rats in average quantities of 15 cc per day, with most gratifying results The animals fed on the irradiated orange juice began to show improvement by the end of five days and the cure was almost complete in a fortnight Those fed on non-rayed orange juice showed no healing, or at most small deposits of calcium salts about some of the cartilage cells, but none in the metaphyses Experiments are now in process to ascertain (1) The antirachitic value of irradiated orange juice in the treatment of rickets in children, (2) the effect of irradiation on the antiscorbutic factor of orange juice, and (3) the length of time during which irradiated orange juice retains its antirachitic properties

Glossopharyngeal Neuralgia—Although glossopharyngeal neuralgia as a clinical entity has been fairly well established during the past few years, but few cases are being reported in the literature. George C Albright (*Laryngoscope*, June, 1926, xxxvi, 6) describes a case of this kind in a woman, aged 66 years, who had been treated for an acute eustachian salpingitis, superimposed upon a chronic dry catarrh of the middle ear, and probably some auditory neuritis. As the improvement following tube treatment was not all that could be desired, the patient's infected tonsils were removed. Following the operation attacks of spasmodic pain developed, which started in the throat, radiating up to the ear, and around the ear, especially over the side of the face. During examination, an applicator pressed against the junction of the palatoglossus with the tongue resulted in acute spasm similar to the attacks the patient was having. Anesthesia of this area relieved the pain. A diagnosis of glossopharyngeal neuralgia was made, and the patient informed that the only relief would be through destruction of the ninth nerve. After consultation with other physicians, who diagnosed trigeminal neuralgia, a tooth suspected of being concerned as a causative factor was extracted and the gasserian ganglion was injected with alcohol. As these measures afforded no relief, the patient consented to section of the roots of the ninth nerve. Albright says that a determination of the exact location of the "trigger area" which exists in most cases, together with a careful study of the distribution of pain, may make the diagnosis certain before surgical procedure is attempted for the relief of what had been diagnosed trigeminal neuralgia.

Fever in the Newborn Infant—F L Adair and Chester A Stewart (*American Journal of Diseases of Children*, June, 1926, xxi, 6) comment on many changes, particularly in the blood, that have been noted in inanition fever. There is a pronounced increase in urea nitrogen and amino-acid nitrogen, especially in those severely ill. A diminished alkali reserve sufficient to produce a decided acidosis is also reported, as well as changes in blood concentration. Bakwin states that fluid given by mouth in proportions of 30 to 40 cc per kilogram of body weight produces a prompt fall in temperature and in the blood concentration. The temperature usually becomes normal in from 30 to 90 minutes after the administration. Relief is obtained much more promptly when fluid is given by mouth than by intraperitoneal or subcutaneous injection. From the authors' present study, it appears that high external temperatures at least influence the incidence of fever among new-born babies. In their series the incidence of inanition fever was far higher from May to September, inclusive. Additional factors contributing to the condition are subnormal fluid intake and excessive loss in weight,

characteristic of babies having fever during the new-born period. The prompt subsidence of the fever on the liberal administration of fluids suggests that dehydration is a very important causative factor.

Double Action of the Vegetative Poisons—By vegetative poison E Barath refers to substances—alkaloids, etc.—which exert a powerful action on the vegetative nervous system comprising the sympathetic and para-sympathetic portions (*Klinische Wochenschrift*, June 4, 1926). Of two forms of double action one which is familiar to us has to do with differences in dosage in which a large dose causes symptoms quite different from those set up by minute doses. With this kind we are not much concerned here. There is, however, quite another type of action, called by the author amphitropic, which is due to the fact that certain drugs are sometimes seen to exert their action at the same time on the sympathetic and parasympathetic, perhaps in different intensities, so that bizarre symptom pictures result. In order to visualize this amphitropism it is necessary to observe the totality of the action of a drug which involves making induced tests. To take a case in point, a solution of 10 per cent calcium chlorate injected in the dose of 5 to 10 cc will cause a temporary slowing of the pulse anywhere from 12 to 35 beats a minute—the author has seen it go as low as 45. This is clearly due to its action on the cardiovagus system, part of the parasympathetic—a typical vagus bradycardia—which can be prevented and immediately antagonized by atropine in small dose. But at the same time it may be found that there is a slight rise of blood-pressure, an increase in the blood sugar, and at times an adrenalin mydriasis—all pure sympathetic symptoms indicating irritability. While the cardiovagus action is brief that of the sympathetic is prolonged. We therefore see here a typical amphitropic action. The latter can also be shown in connection with atropine and adrenalin and explains certain irregular and atypical drug actions—how a drug which ought to slow the pulse may exceptionally quicken it. This principle explains the occasional dissociation of a certain symptom picture, for while ordinarily adrenalin increases both blood sugar and blood pressure, exceptionally the sugar will increase while the blood pressure falls.

Hereditary Hemorrhagic Telangiectasia—Charles Mallory Williams reports in the *Archives of Dermatology and Syphilology* for July, 1926, four cases of this condition, the essential symptoms of which he enumerates as follows: (1) The occurrence of nosebleed in childhood, often recurring throughout the life of the patient, and sometimes associated with bleeding from other mucous membranes, or even, after traumatism, from the skin. The bleeding may decrease as the

patient grows older, or may become more and more serious and finally prove fatal (2) The development of telangiectasæ, sometimes as dilated capillaries, sometimes as a network of dilated venules, more characteristically as spider nevi, occurring sometimes in youth, more often in adolescence or adult life, and usually increasing with the passing years (3) The occurrence of these symptoms in several members of the family Usually the same individual presents both groups of symptoms, but sometimes one group or the other may be missing in an individual case Williams says that, while this disease has hitherto been regarded as one of great rarity, his experience leads him to look upon it as exceedingly common He thinks its frequency would soon be established if every physician seeing a spider nevus would ask about the occurrence of nose-bleed in the patient and in other members of the family

Influence of Insulin in Cancer—V R Stuhler refers to the work of Warburg in showing that the cancer cell splits sugar with formation of lactic acid and to his generalization that there can be no growth without glycolysis Insulin has been administered in various forms of experimental cancer and apparently always with inhibition of cancer growth Given in advance of implantation it shows the same inhibitory action It will be remembered that if sugar and adrenalin are simultaneously injected cancer growth is stimulated The author tested insulin injections in 14 patients with inoperable cancer, mostly recurrent The remedy was pushed by giving relatively small doses daily for several weeks In 12 of these cases no inhibitory action was shown, but in the other two such action was present in a remarkable degree The cancers in these cases were situated on the face and while very destructive could hardly be compared in severity with cancer of the cervix and breast Cancer is now generally held to produce (or is it, to result from) a disturbance in the carbohydrate metabolism, and in nearly all cases, if not all, there is an increase, however slight, in the blood sugar Any general remedy which will antagonize cancer will, the writer believes, probably reduce the percentage of blood sugar This was evident in the two cases benefited by insulin but naturally it is the function of insulin to reduce blood sugar in all individuals treated Judging from the two cases the patient, to benefit by insulin, ought to be undernourished, for in these cases the remedy caused the patients to take on a few pounds of weight—*Wiener klinische Wochenschrift*, June 17, 1926

Loss of Weight as an Early Symptom in General Paralysis—In the course of a study of

74 cases of general paralysis of the insane, made with a view to determine the primary symptoms of this condition, Henry A Bunker says that he was impressed by the relative frequency with which loss of weight was mentioned among the early symptoms of the condition Thirty-eight of these seventy-four patients suffered from loss of weight at some time subsequent to the earliest signs of the onset of the paralysis, but prior to the necessity for their commitment, and of these thirty-eight, the loss of weight was essentially the earliest abnormality noted in twenty-two In twelve of the thirty-eight patients there was also a history of bulimia developing some time after the commencement of the loss of weight which in a few cases was successful in counterbalancing that loss to a considerable extent The author suggests the possibility of a relationship of these findings to the therapeutic response of the patients, since the greater number of those who regained their weight by the increased food intake responded very favorably to treatment, while four in whom treatment was of no avail had bulimia but did not thereby regain their weight—*Archives of Neurology and Psychiatry*, July, 1926, vi, 1

Irradiated Orange Juice—As experience in the use of ultraviolet light grows apace it is found to possess many virtues and powers which were unsuspected in the beginning Not the least interesting of these discoveries is the power of these rays to impart antirachitic properties to substances not previously capable of preventing or curing rickets Among the substances which can acquire antirachitic efficacy through exposure to ultraviolet light is milk In searching for an agent which would be at once antiscorbutic and antirachitic H L Maslow, D H Shelling, and B Kramer (*Bulletin of the Johns Hopkins Hospital*, xcxix, 1, July, 1926) experimented with rayed orange juice They employed a concentrated orange juice, one part in two parts of distilled water, irradiated for three hours under a mercury vapor quartz lamp at a distance of 18 inches This was fed to rachitic rats in average quantities of 15 c.c. per day, with most gratifying results The animals fed on the irradiated orange juice began to show improvement by the end of five days and the cure was almost complete in a fortnight Those fed on non-rayed orange juice showed no healing, or at most small deposits of calcium salts about some of the cartilage cells, but none in the metaphyses Experiments are now in process to ascertain (1) The antirachitic value of irradiated orange juice in the treatment of rickets in children, (2) the effect of irradiation on the antiscorbutic factor of orange juice, and (3) the length of time during which irradiated orange juice retains its antirachitic properties

LEGAL

By LLOYD PAUL STRYKER, Esq
Counsel, Medical Society of the State of New York

THE DOCTOR AND THE WILL

All of us must die, and yet so repellent and unnatural is the thought to the average normal person that many, who otherwise throughout their lives have been alert in safeguarding their property and the interests of those dependent upon them, neglect until the final hour one of the most important duties of their lives—the making of a will

Throughout the last illness and in the final hour there is usually a doctor present. Because of the close and confidential relation which the physician occupies to his patient, it happens not infrequently that the doctor is called upon to perform some act in connection with the preparation or execution of the most important document which any of us can ever make—the Last Will and Testament. Usually at a time of this kind there is no lawyer present, and no one to advise as to the necessary formalities, and the doctor, who oftentimes is looked to by the family as a wise counsellor not only in his chosen field but in many others, is called upon at this critical time to assist in this most difficult, solemn and important act. It has occurred to us, therefore, that a statement of the simpler rules of law applicable to will-making might not be unacceptable to the medical profession

Before doing this it might be well to answer the question: Why make a will at all? The answer is that if no will is made, then the decedent's property, both real and personal, is distributed in accordance with the statute, which oftentimes may not produce the result desired, by failing fully to award to those whom the dying person would like to make the objects of his bounty

Who may devise real property? The law says that "all persons except idiots, persons of unsound mind, and infants, may devise their real estate, by a last will and testament, duly executed, according to the provisions of this article"

What is the rule in regard to personal property? Again the law is clear: "Every male person of the age of eighteen years or upwards, and every female of the age of sixteen years or upwards, of sound mind and memory, and no others, may give and bequeath his or her personal estate, by will in writing"

Having determined who may make a will, the next question is: How shall that will be made in order to render it a valid instrument?

In the first place a will must be in writing. The only exception to this rule is in the case of a soldier or sailor, either of whom may make a verbal will under conditions which the law has also plainly stated in these words:

"No nuncupative or unwritten will, bequeathing personal estate, shall be valid, unless made by a soldier in actual military service, or by a mariner, while at sea"

As this is a contingency with which the average physician will be seldom called upon to deal, we shall pass to a consideration of the necessary requirements for a valid written will. There is no mystery about this, and yet the requirements for a valid will are definite and specific, and must be complied with. The law says that:

"Every last will and testament of real or personal property, or both, shall be executed and attested in the following manner:

"1 It shall be subscribed by the testator at the end of the will

"2 Such subscription shall be made by the testator in the presence of each of the attesting witnesses, or shall be acknowledged by him to have been so made, to each of the attesting witnesses

"3 The testator, at the time of making such subscription, or at the time of acknowledging the same, shall declare the instrument so subscribed to be his last will and testament

"4 There shall be at least two attesting witnesses, each of whom shall sign his name as a witness, at the end of the will at the request of the testator"

The law is wise and there is always a reason behind it. The object of these statutory requirements prescribing the manner in which wills must be executed is, as has been said by our Court of Appeals:

" * * * to throw such safeguards around those transactions as will prevent fraud and imposition, and it is wiser to construe these statutes closely, rather than loosely, and so open a door for the perpetration of the mischiefs which the statutes were designed to prevent"

The requirements of the statute are important, they must not be disregarded, for our highest court has said that the intention of the legislature and not that of the testator, must be considered in construing this section, and failure to observe some one or more of these requirements defeats the will, even though an honest attempt to execute it properly is made.

The law, as we have seen, requires that the will "shall be subscribed by the testator at the end." There is no requirement that it be sealed, either in the case of real or personal property, but the will, in order to be valid, must be signed by the testator *at the end*. Thus it has been held that a marginal interlineation in a will, extending below the testator's signature and disposing of property, upon the happening of certain events, in the same manner in which it would be disposed of by law, may be disregarded as immaterial, and the portion of the will above the testator's signature admitted to probate.

Again, as we have seen, the subscription of the testator must be made by him "in the presence of each of the attesting witnesses" or "shall be acknowledged by him to have been so made to each of the attesting witnesses."

In order to avoid complication the testator should sign his name at the end of the will, in the presence of both of the attesting witnesses. This is true even though it has been held that it is not necessary that a witness should actually see a testator sign his will, if the testator's signature is affixed in the actual or constructive presence of the witness. Thus in one case it was held sufficient that the witness was in an adjoining room with the door open when the testator signed and could have seen him subscribe his name. Such a practice, however, is dangerous, and the proper procedure is that the attesting witnesses should actually see the testator in the act of signing the will.

In all cases, where possible, the signature should be made by the testator with his own hand without assistance, although it has been held that a testator's signature is sufficient and complies with the law if, being physically unable to sign his name, he calls upon another to assist him, even to the extent of holding and guiding his hand, so long as it is his wish that his signature be thus made and he acquiesces in it and adopts it. It has even been held that a signature by mark is sufficient where the testator was aged, deaf and blind, or where he could not read and write. A will so subscribed, however, is an invitation to attack. The safe practice is that the signature should actually be written by the testator with his own hand and without assistance.

Again, we have seen that the testator, at the time of subscribing the will or at the time of acknowledging the same, "shall declare the instrument so subscribed, to be his last will and testament." There is a purpose in this provision, as in all the rest. Subscribing witnesses to a will are required by law for the purpose of attesting and identifying the signature of the testator and that they cannot do unless, at the time of the attesting, they see it. Hence it has been held that although a testator acknowledges to attesting witnesses that an instrument is his last will, there is no proper execution of the will if, at the time he signs it, it is folded in such a manner that his signature is not visible to them. The testator must sign the will before the attesting witnesses attest the same. Thus in one case it was decided that the subscription to a will by a testator after the attesting witnesses had signed their names to it was not a due execution of it.

Again, we have seen that there must be "at least two attesting witnesses," and that each of these "shall sign his name as a witness, at the end of the will at the request of the testator." In this provision there are, then, three requirements: (a) that the attesting witness sign his name as a witness, (b) that this be done "at the end of the will", and (c) that it be done "at the request of the testator." Each of these requirements must be carried out literally. At the bottom of the will, after the testator's signature, there should be an attestation clause of which the following is a valid form:

"Subscribed, sealed, published and declared by the above named testator (or testatrix in the case of a woman)

(name)

as and for his last will and testament, in the presence of us and of each of us who, in his presence and at his request, and in the presence of each other have hereunto subscribed our names and addresses as attesting witnesses this _____ day of

_____, in the year of our Lord, one thousand nine hundred and twenty_____

Name

Address

There is one additional requirement which must be observed. It is expressed by the statute in these words:

"The witnesses to any will shall write opposite to their names their respective places of residence, and every person who shall sign the testator's name to any will by his direction, shall write his own name as a witness to the will. Whoever shall neglect to comply with either of these

provisions shall forfeit fifty dollars, to be recovered by any person interested in the property devised or bequeathed, who will sue for the same. Such omission shall not affect the validity of any will, nor shall any person liable to the penalty aforesaid, be excused or incapacitated on that account, from testifying respecting the execution of such will."

In cases where an attack upon the will might reasonably be anticipated, either by reason of the claim of undue influence or lack of testamentary capacity or on other grounds, compliance with the provision added to the statute by the legislature in 1923 would be of material assistance to those seeking to resist such an attack. This section provides that

"A subscribing witness to any last will or testament may make and sign an affidavit before any officer authorized to administer oaths setting forth such facts as he would be required to testify to in order to prove such will. Such affidavit may be written upon said will, or on some paper securely attached thereto, and may be filed for safe keeping with the last will or testament to which it relates."

Where an attack upon the testator's capacity is anticipated and there is sufficient time and opportunity, it would be wise to have the testator examined by two physicians who are certified medical examiners under the Insanity Law. The new provision of the statute on this subject is

"There may also be filed with such will, affidavits of certified medical examiners, under the provisions of the insanity law, certifying that the maker of said will was of sound mind at the time of its execution, together with any facts supporting such opinion."

While the statute of the State of New York requires but two attesting witnesses, in the statutes of some other states three attesting witnesses are required. It would therefore be wise to inquire whether or not any of the real property devised is situated in other states, in which case it would be a wise expedient to have three, instead of two, attesting witnesses.

It oftentimes occurs that those about the bedside of the dying person or in attendance upon him during his last illness and who might reasonably be expected to act as his attesting witnesses, are those who are intended to participate in the testator's bounty. These facts should be inquired into, because a person who is to be a beneficiary under the will cannot be an attesting witness without forfeiting his legacy or devise. The law upon this subject is

"If any person shall be a subscribing witness to the execution of any will, wherein any beneficial devise, legacy, interest or appointment of any real or personal estate shall be made to such witness, and such will cannot be proved without the testimony of such witness, the said devise, legacy, interest or appointment shall be void, so far only as concerns such witness, or any claiming under him, and such person shall be a competent witness, and compellable to testify respecting the execution of the said will, in like manner as if no such devise or bequest had been made."

"But if such witness would have been entitled to any share of the testator's estate, in case the will was not established, then so much of the share that would have descended, or have been distributed to such witness, shall be saved to him, as will not exceed the value of the devise or bequest made to him in the will, and he shall recover the same of the devisees or legatees named in the will, in proportion to, and out of, the parts devised and bequeathed them."

In the making of a will one of the most important matters is the choice of an executor. The executor is the trusted representative of the testator. He is the person selected to carry out and administer the wishes of the deceased. He should therefore be a competent and trusted person, and latterly it has been regarded as a wise practice to appoint a trust company and an individual as co-executors. In this way the estate receives the benefit of the financial advice and management such as only a trust company can render, and also the personal interest of the individual who has been selected as the co-executor. The testator may select a trust company to act as his sole executor, or he may select an individual to act in that way. If an individual is selected he must be over the age of twenty-one years, he cannot be an adjudged incompetent, an alien, a non-resident of the state, a felon, or a person incompetent to execute the duties of the trust by reason of drunkenness, dishonesty, improvidence or want of understanding.

In this article, of course, there has been space only in which to indicate a few of the most important principles surrounding the making of a will. It is hoped that these may be not without interest to the medical profession. If interest in this discussion is evinced, we would be pleased to pursue the subject in some further article. There are many fascinating subjects which might be of interest to the doctor, among which are the great questions of undue influence and in-

sanity or other mental incompetence which would render a will invalid. The physician, by the nature of his trusted relationship to patients, is frequently thrown in contact with the law. As with the lawyer, there is no subject the knowledge of which may not be beneficial to him in his practice.

It is the purpose in these editorials, so far

as is possible, to talk of subjects which may be of interest to the profession. Your counsel will welcome advice or suggestion along this line. If there is any subject which physicians feel they would like to have discussed and upon which they feel their counsel would be competent to throw light, he will be glad to take up the topics suggested.

BRONCHIAL PNEUMONIA—RESOLVING OTITIS MEDIA

A physician was called to attend a child about two years of age. Upon examination he found her with a temperature of about 103 degrees and respiration of about 56, with a history of twenty-four hours' illness accompanied by temperature, fast respiration and pain in the ear. Upon a complete examination, with the use of the stethoscope, the presence of rales was found in the entire chest, particularly in the right side. Examination of the right ear disclosed a congested drum. After examination a diagnosis was made of bronchial pneumonia. *Liquor ammonii acetatis* was prescribed, the use of mustard plasters to the chest and syringing of the ear, and the mother was advised to give the child sponge baths. Two days thereafter he found the right hand swollen and did not determine the cause of this condition.

Another physician was then called to attend the child. The defendant saw the child once in consultation with the second physician, at which time the previous diagnosis was confirmed and it was suggested that the ear drum be watched. Thereafter the defendant was advised that he need not call again.

The second physician made a thorough examination of the child and a diagnosis was made of influenza and pneumonia with resolv-

ing otitis media. The swelling of the right hand was unexplained but did not suggest pus or rheumatism, but was possibly due to anaemic condition. The second physician attended the child for eight or nine days, when a third physician was called in, who made a diagnosis the same as the first two physicians, but after three or four days of observation of the ear, decided that an abscess had formed, and that it would be necessary to open the same, and thereupon called in a surgeon to perform the operation. The surgeon opened up the abscess, placed some drains therein, and left the care of the patient in the hands of the third physician. The bronchial condition cleared up while under the care of the third physician.

Thereafter an action on behalf of the child and the father's action for loss of services were instituted against the first physician, charging him generally with negligence and carelessness, and the lack of proper judgment in his examination, diagnosis and treatment of the infant plaintiff, and that by reason of such alleged negligence the sickness of the child was prolonged and increased and his health permanently impaired.

When these actions came on for trial, the plaintiffs failing to appear in the prosecution thereof the complaints were dismissed.

NEWS NOTES

THIRD DISTRICT BRANCH

The Twentieth Annual Meeting of the Third District Branch of the Medical Society of the State of New York will be held in the Auditorium of the Harmanus Bleecker Library, corner of Dove Street and Washington Avenue, Albany, N Y, Saturday, September 25th, 1926

Program

10 A M (Daylight Saving Time)

Address of Welcome

William P Howard, M D, President, Albany County Medical Society

Presidential Address

Charles P McCabe, M D, Greenville, President, Third District Branch

Address Post-Graduate Education

Henry J Noerling, M D, Balatie, President, Columbia County Medical Society

Address Periodic Health Examinations

Haven Emerson, M D, New York City

Address Medical Legislation and the Webb-Loonius Bill Henry L K Shaw, M D, Albany, Chairman Legislative Committee, Medical Society of the State of New York

Address

William P Howard, M D, Albany

X-ray conference, round table discussion

LUNCHEON, 1 P M

The Members of the Branch are invited to luncheon at the Fort Orange Club as the guests of the Albany County Medical Society

AFTERNOON SESSION, 2 P M

Address George E Fisher, M D, Utica, President, Medical Society of the State of New York

Address James L Sadler, M D, Poughkeepsie, President-elect, Medical Society of the State of New York

Address Daniel S Dougherty, M D, New York City, Secretary, Medical Society of the State of New York

Address Joseph S Lawrence, M D, Executive Officer, Medical Society of the State of New York

Address William A Howe, M D, Albany, State Education Department

SOCIAL, 5 P M

Annual Clambake of the Albany County Medical Society at McKown's Grove, Western Turnpike, at 5 o'clock All members of the Third District Branch and their wives are cordially invited Tickets at \$5 00 each

PROGRAM FOR THE LADIES

The wives of the members and the women members of the Branch will be entertained at Luncheon at the Albany Country Club, Western Turnpike, at one o'clock by the wives of the members of the Albany County Medical Society The afternoon will be spent at the Club, and at 5 P M adjournment will be taken to the McKown's Grove for the Clambake

TRANSPORTATION

Transportation will be provided for the members of the Branch and their wives both to the Country Club and also the Clambake, if so desired Western Avenue buses go by Harmanus Bleecker Library, the Country Club and McKown's Grove

SENECA COUNTY MEDICAL SOCIETY

The Semi-annual meeting of the Seneca County Medical Society was held at the Citizen's Club, Seneca, on Thursday, May 13th

The morning business session was followed by a luncheon at the Gould Hotel after which the Society reconvened for a scientific session

Dr J M Swan, in charge of the publicity work in New York State, of the American Society for the Control of Cancer, spoke on the role of the private physician in the early diagnosis and prevention of cancer A very interesting discussion, led by Dr Elliott, followed Dr Swan's remarks

The Society was then addressed by Dr John

R Williams, of Rochester, who spoke on "High Blood Pressure" Dr Williams gave the modern conception of high blood pressure, spoke interestingly of the experiments he carried out while in Toronto, and of the treatment of patients with this condition, emphasizing, especially, keeping these patients within normal weight limits, and giving them plenty of rest He spoke of associated conditions of nephritis and arteriosclerosis and emphasized the importance of the specific gravity of day and night urine as indicative of serious renal impairment, if it does not vary

Dr Lester W Bellows, Waterloo, N Y, read a very interesting biography of Dr Coventry, the second practising physician of Seneca County

SUFFOLK COUNTY MEDICAL SOCIETY

1 The Semi-Annual Meeting

The regular semi-annual meeting of the Suffolk County Medical Society was held in the Old Oak Hotel, Patchogue, on Tuesday, May 18th, 1926, with thirty-eight members and seven guests present. The President, Dr J S Ames of Babylon, presided.

On motion the Society voted to request the State Medical Society to hold its next meeting in Niagara Falls.

The Society voted to approve the anti-diphtheria campaign that is promoted by the Medical Society of the State of New York, the State Department of Health, and the Committee on Tuberculosis and Public Health of the State Charities Aid Association.

The Treasurer, Dr David H Hallock, reported that the present paid-up membership of the Society was 110. The amount of dues collected during the past fiscal year at five dollars each was \$546, and that \$1,215.03 remained in the treasury. The two principal items of expense were \$233.15 for the Monthly News Letter—the eight-page publication of the Society—and \$95 for clerical hire for the Secretary.

Dr Guy H Turrell, Editor of the News Letter, sent a brief report of the publication, and especially urged the associate editors to send more items from their respective districts.

Dr W H Ross, Chairman of the County Committee on Tuberculosis and Public Health of the State Charities Aid Association, suggested a tentative plan of enlarging the scope of the Society's News Letter, and publishing it more frequently by permitting the Tuberculosis Committee and other health organizations to use its column for news and publicity, part of the increased cost to be borne by the other organizations. Considerable discussion followed, all favorable to the suggestions, and the following motion was unanimously carried:

Whereas, There exists an opportunity to advance practical medicine, foster the material and economic interests of the medical profession, and promote public health by expanding the Monthly News Letter of the Suffolk County Medical Society, therefore

Be It Resolved, That the Suffolk County Medical Society be authorized to receive any funds donated by health or other organizations, or from private sources, for the purpose of expanding and publishing semi-monthly, or more often, the News Letter of the Suffolk County Medical Society.

The following new members were elected:
Dr Louis C Grytie, Patchogue

Dr Grover A Silliman, Sayville

Dr Katherine G Brockman, Kings Park

Dr Charles R Gannaway, Kings Park

Dr William E Glanville, of Bridgehampton, was accepted as a member by transfer from the Nassau County Medical Society.

Mr A Royce Wolfe, County Secretary of the Boy Scouts, was present by invitation, and spoke briefly on the instruction in first aid that is given to every scout. He asked the cooperation and influence of the Medical Society in giving a standard form of instruction. This matter was referred to the Committee on Public Health with the understanding that standard methods in first aid should be presented through the columns of the Monthly News Letter.

After the business of the Society had been transacted the members and guests dined together at one o'clock, and then convened for a scientific program. The general subject discussed was the group of chronic diseases that affect the joints, kidneys and heart—a subject that was broad and included many related conditions.

Dr W H Ross gave a preliminary report on studies which he and Dr P A Williams had made on the relation of diet to arthritis, diabetes, and kidney diseases. The two physicians had observed twelve cases of chronic arthritis with great care, and had found incipient diabetes, nephritis, and heart involvement in them in varying degrees. They had kept the patients on a diet that was restricted, especially in carbohydrates, and had made sustained studies in calories, blood chemistry, and urine, and had balanced the incomes and outgoes of the bodies of the patients to their great benefit. Further reports of this series of cases will be made.

A further development and application of the points presented by Dr Ross was made by Dr Blake F Donaldson of New York City, who demonstrated two cases of cardio-nephritis supplied by Drs W W Gardner and L J Barber. One was in the incipient stage, and his disease was probably caused by wrong eating, especially an excess of salt and carbohydrates. This case was already improving under dietary directions and instruction.

The second case was an elderly woman with a blood pressure over 300, and clear evidences of sclerosed kidneys and arteries. This case had progressed so far that a anatomical replacement of the sclerosed tissue was impossible, and the patient will be happier if she is allowed to have her own way in dieting and other details of living.

2 The Comitia Minora

The Comitia Minora of the Suffolk County Medical Society met on the afternoon of July 29th, in the bungalow of Dr W H Ross, at Fort Salonga, with the eight physicians present

The President, Dr J S Ames, stated that the principal object of the meeting was to take action on an offer of the Suffolk County Committee on Tuberculosis and Public Health to assist the Medical Society in financing its Monthly News Letter up to about one thousand dollars annually

Dr W H Ross suggested that the News Letter embody the following features

1 It shall supply the public with medical news which the people could understand

2 It shall describe the activities of the County Medical Society, the Committee on Tuberculosis and Public Health, the Board of Child Welfare, the local Boards of Health, the school medical examiners, and other agencies doing public health work in the County

3 It shall state the attitude of the physicians of Suffolk County toward public health subjects, such as pure milk, water supply, sewage disposal, hospitals, and other public projects in which health is involved

4 The County Medical Society shall continue to have control of the News Letter as in the past

After considerable discussion of the details of the proposals of Dr Ross, all favorable, they were unanimously adopted and a committee of three was authorized to carry out the details of the plan. The President appointed Drs W H Ross, Guy H Turrell, and F Overton such committee

The periodic examination of persons apparently healthy was next discussed. It was felt that the time had come when the Society should promote the examinations, and it was suggested that the doctors could show their sincerity in the best way by each one submitting himself to an examination by a medical colleague of his own choosing. It was unanimously voted to adopt the plan as a major activity of the Society, and that a committee of three be appointed to carry out the details of the plan. The President appointed Drs P A Williams, G H Schenck, and A G Turrell as the committee

It is planned to use the A M A blanks, to send two copies to each doctor, and to ask each doctor examined to send a copy of the report to the committee for tabulation and study

The subject of pure milk in Suffolk County, which had been discussed at nearly every meeting of the County Society recently, was brought up because of recent disclosures that "bootleg" milk was being brought into the County from up-State and New Jersey, and was being sold without the dealers obtaining permits or disclosing the sources of their supply. Moreover, several cases of infant sickness had been traced to milk labeled "Grade A," "Pasteurized," which had turned sour before night on the day it was bought. The opinion of the members of the Comitia Minora that a series of articles stating the principles of pure milk supply be printed in the News Letter, and that the Public Health Committee should promote the establishment of means by which bacterial counts of milk might be made in the County

3 The Public Health Function of a County Medical Society

The public health function of a county medical society is stated in the following editorial by Dr W H Ross in the August News Letter of the Suffolk County Medical Society

"The Medical Society of Suffolk County can perform no more important work, nor fulfill its reason for existence better than to advocate measures for the protection of public health and to devise means to make them effective

'To stimulate development of any sound health program for the protection of the health of the County should be a major function of organized medical effort. To arouse the interest of the public generally regarding prevention of disease and to secure ultimate acquiescence by the public, it is as necessary to advertise what can be done as it is to advertise, as an example, anything for sale

"The effectiveness of any effort in health or welfare lines, so as to secure individual, community or county governmental support depends upon the demands of public opinion in these respects

'It is expected that the News Letter of the Suffolk County Medical Society and of the Health and Welfare Organizations of Suffolk County, may become the official means of developing health education in the prevention of disease and the protection of the health of its citizens under all conditions and at all ages"

THE DAILY PRESS

PREPAREDNESS

Preparedness has many other phases besides that of military defense. There is also defense against epidemics. A great epidemic is unlikely, but like war, it comes unexpectedly and in unfamiliar forms. The great epidemic of infantile paralysis in 1916 found the entire community as unprepared and as helpless as it was against attacks of cholera and yellow fever a century ago, and neither the medical profession nor the people are now better prepared than they were a decade ago.

It is commendable that Health Commissioner, Dr. Louis I. Harris, has started a movement in medical preparedness. A news item in the New York Sun of August 5th, says

"A plan to be prepared in case of a visit to

the city of epidemics such as the influenza scourge of 1918 is being worked out under the sanction of the Mayor's Committee on Hazards and Emergencies. It aims to offer the hospitals, health agencies and other groups, a course of action which can be immediately put into effect in case of the sudden appearance of an epidemic. The studies now being made will be completed before October 1. The Mayor's Committee will be asked to ratify the plan of attacking the phantom epidemic after Dr. Harris has worked it out on the basis of a study now being made by Dr. Hollis L. Godfrey. The sum of \$3,850 has been raised for the preliminary study by public subscription. The total cost of the survey is estimated at \$12,000."

THE STAGGER PLAN OF TRAVEL IN NEW YORK CITY

The New York Herald-Tribune of August 5th describes the further development of the plan to relieve crowding in the transportation system of New York City. The project is in charge of a committee under the Department of Health, consisting of Dr. Louis I. Harris, Health Commissioner, Dr. Louis I. Dublin, statistician of the Metropolitan Life Insurance Company, who is in charge of the census, and Major Philip H. Mathews, executive officer of the Transit Commission.

The Committee has listed the following industrial units for the purpose of the investigation:

The list of industrial units agreed on by the committee for the main manufacturing groups is as follows: (1) men's wear industry, (2) women's garment industry, (3) millinery and lace goods, (4) fur and fur goods, (5) leather goods, (6) jewelry, (7) paper products, (8) printing, publishing and bookbinding (not including newspapers), (9) furniture, (10) house furnishings, (11) pianos, (12) metal industry.

Minor manufacturing industries include (1) chemicals, paint, oil, drugs, proprietary medicine and cosmetics, (2) tobacco and allied products, (3) vehicles and allied lines, (4) stone, clay and glass products, (5) textile manufactures, (6) miscellaneous manufactured products.

Wholesalers and jobbers fall into seventeen divisions, as follows: (1) silk textiles, (2) woolen textiles, (3) cotton textiles, (4) carpets and rugs, (5) knit goods, (6) electrical sup-

plies, (7) food products and cold storage plants, (8) millinery, (9) fur and fur goods, (10) leather goods, (11) jewelry (when so specified), (12) coffee, tea and spices, (13) drugs, chemicals and proprietary medicine, (14) shoes, (15) hardware, (16) furniture, (17) miscellaneous wholesalers.

Under retail trade department stores will be placed in one group and all retail stores in another. Building employees and building maintenance and service are grouped together.

Manhattan's clerical force will be divided into the following classes: banks, insurance, stock brokers and investment houses, and other clerical, executive and professional groups.

Industries belonging to the group doing a twenty-four hour business, such as newspapers, garages, hotels, power houses and restaurants, will be treated as a separate subdivision.

The New York Herald-Tribune of July 20 contains a brief preliminary report on the first 500 forms which were filled out by employers. The report says:

"Among the discoveries which surprised those taking the census was the large percentage of workers who walk to work. Eighteen out of the 106 employees of the United States Tobacco Company walk to work. 11 of the 56 at Leo Feist's music publishers, walk. 25 of the 120 at the Century Company, publishers, walk, and larger percentages were tabulated for some firms."

Already differences of opinion are developing, and American independence is asserting itself. One employer is quoted:

"We believe that the hours of nine to five belong by priority right to office workers. The hours of nine to five are the most convenient and the best hours of work for many reasons. More recently, textile workers and the employees of dry goods stores have usurped these hours. If any readjustments are to be made, those who have come last to these hours should do the readjusting in all fairness."

Either indifference or American independence, in an exaggerated form, is delaying the census of travelers within the city. The New York Sun of August 18th comments on the slowness of the responses and says:

"Mayor Walker stepped into the emergency today and made public a statement appealing to business men to take an active interest in the 'stagger census' and have the census blanks compiled at the earliest date. Only 400,000 returns have been received and the least calculation is

that the transit movement of 1,000,000 workers must be analyzed before an adequate system can be mapped.

"The returns are all classified and office forces have been provided for the swift assortment of the cards. They are then turned over to experts for analysis and interpretation. Several trends in subway travel not hitherto realized have become apparent from the studies made so far. The full data will make it possible to learn the travel habits of the bulk of Manhattan's workers, so that the plans devised for relief will be based upon known facts."

The New York Herald-Tribune of August 19th says in an editorial entitled "Slackers":

"Some people have not enough interest in the present situation to take the little trouble to improve it which is asked of them. The lack of transportation in New York is not wholly the fault of those who have had to deal with it. A large part of it is due to the refusal of the public to do their share—as they are refusing in the present instance."

HEREDITY VS TRAINING

The following clipping from the New York Herald-Tribune bears on the much discussed subject of the relative values of heredity and training as incentives to action:

"The younger generation of pullets in the poultry families of Middletown, N. Y., are not wastrels, but serious-minded young hens, intent on being good mothers. A farmer has a pullet less than seven months old which has stolen a nest, laid fourteen eggs and hatched fourteen chickens. The pullet never had the advantage of being well brought up by a competent old hen. It was one of 200 orphans hatched in an incubator."

Inherited traits are always to be considered in judging the reasons for any given action.

A tame crow will always be mischievous and thieving no matter how much it be trained, and so will some human kleptomaniacs. Jail birds will repeat their crimes over and over whenever they get the chance and no amount of training or expressions of sorrow will change them. The children of some families will lead straight lives under trying temptations, and those of other families cannot be trusted with any chaperon. But the fact remains that the great mass of human beings are amenable to suggestion and training and are anxious to adapt themselves to society. It is quite the style and custom to adapt one's self to the standards of politeness, which after all, are founded on morals and righteousness.

A DISPELLER OF HUMBUG

The New York Herald-Tribune of August 9th contains an editorial commending the work of one of the world's great "Magicians" in exposing the claims of miracle workers. The editorial says:

"Many pretenders, who were seven-day wonders, even exciting the interest of fairly intelligent persons, have been exposed by this rational and energetic man. He is really an apostle of intelligence.

"An Egyptian mystic, whose exploits have caused some little stir among those who have seen

him recently, had himself sealed up in a casket and remained under water for an hour. He asserted that he could do this because of his power of suspending his own animation for that period—'going into a trance' and remaining temporarily dead.

"Houdini did not go into a trance. He merely, by careful breathing, conserved the oxygen supply in the casket, and lived by its means until the end of an hour and a half. Credulity is still too common among the wonder-loving race of human beings."

NEW YORK STATE JOURNAL of MEDICINE

PUBLISHED BY THE MEDICAL SOCIETY OF THE STATE OF NEW YORK

VOL 26, No 18

NEW YORK, N Y

September 15, 1926

THE EXPERIMENTAL PRODUCTION OF LUNG ABSCESS*

By S A. SCHLUETER, M.D., I. F. WEIDLEIN, M.D., and E. C. CUTLER, M.D., CLEVELAND, O

THIS study of lung abscess was made as a part of a general investigation of postoperative pulmonary complications. It, therefore, concerns chiefly the type of pulmonary suppuration occurring under these conditions, although our ability to create lung abscesses experimentally allows us the opportunity to study the pathological development, course, and subsidence or final disastrous result in any abscess once it is established. In view of our interest in postoperative pulmonary complications, it will be obvious to you that we were chiefly concerned with the manner by which such postoperative

treatment of lung abscess as compared to the few careful studies devoted to its mode of origin.

It is commonly accepted that there are two chief groups of lung suppuration, one developing within the bronchial tree, and one developing within the lung tissue, the latter type at least commencing as a real parenchymatous abscess not in connection with the air passages (1). With the extension of any abscess, the bronchial tree is finally opened into so that gross pathological studies will never give evidence of the initial stage of the disease. We believe that the type of abscess occurring as a postoperative complication starts as a true parenchymatous lesion. To support this view we bring the evidence 1, that other postoperative pulmonary complications are of embolic origin (2, 3), and 2, that we can reproduce lung abscess experimentally by the use

FIG 1—Method of preparing vein embolus. Shows section of femoral vein, tied at one end, other end open lead hling and culture have been placed in this sac and upper end is about to be tied. Embolus is then ready for placement in vein.

lung abscesses arise. We feel that, until the etiological factors responsible for the production of a lung abscess are at hand therapy cannot rest on sensible grounds. And yet the information now available shows that an immense amount of effort and study has been expended in the

FIG 2—Method of introducing embolus into jugular vein. Shows jugular vein held out of wound with threads and glass cannula containing embolus placed in opening into vein pointing toward the heart. Salt solution forced into cannula from syringe will push embolus down the vein when lower traction thread is released. Opening in vein is then sutured or the vein is ligated.

*Read before the New York State Medical Society, March 31, 1926. From the Laboratory of Surgical Research, The Lakeside Hospital and the Western Reserve Medical School.

of infected emboli which result in a true parenchymatous lung abscess, whereas no one has ever successfully reproduced typical lung abscess in laboratory animals by the instillation of infected foreign bodies and infected tissue into the air passages. Those familiar with bronchoscopic work (4) have reiterated the great dissimilarity between the pulmonary suppuration which sometimes accompanies a foreign body in the air passages and true lung abscess. The facts that patients have carried large foreign bodies in their

to lead us to feel that infection played a dominant rôle.

2 These complications occurred in almost equal percentages whether local or inhalation anesthesia was used.

3 The frequency of occurrence of the complications seemed to vary not according to the age or type of the individual, nor with any external conditions, but according to the seat of the operation. And here it seemed to vary according to the mobility of the part. Thus, a conservative estimate will give postoperative pulmonary complications in two per cent of general operations. In operations upon the brain where the skull acts as a definite splint, the percentage is almost nil. The percentage for the general abdominal cavity is around five to six per cent, but in the epigastrium, where each breath moves the part, the percentage rises to eight per cent.

We are entirely conversant with the ideas and reasoning of those who support the aspiration-irritation theory as to the production of these lesions. We recognize that in every operation, as has been shown experimentally (6, 7, 8) and clinically (9), there is aspiration of mouth contents. We know that the inhalation of sputum spray apparently reduces the resistance to infection. But we also know that elaborate preoperative measures aimed at cleaning the mouth and the use of buccal suction during the operation

FIG 3—Dog Y 16 Roentgenogram immediately after freeing an embolus into the jugular vein. The lead film demonstrates lodgment of the embolus in the left lower lobe.

bronchi for many years with little more in the way of symptoms than a chronic, productive cough and that there is almost immediate relief in these cases with removal of the foreign body are arguments against calling this type of lesion a lung abscess. Although a localized bronchial suppuration may be produced in this way, the lesion consists chiefly of endobronchial irritation caused by the foreign body and rarely results in extension into the parenchyma to form a true lung abscess. Lung abscess can be produced by freeing infected emboli into the blood stream. We feel that this is the explanation for the type of abscess seen as a postoperative complication. It may be the explanation for the major number of all lung abscesses and is, in our minds, the explanation for all those that originate as parenchymatous lung abscesses.

For a long time we have been interested in the etiology of postoperative pulmonary complications, and after years of study were forced to the conclusion that the majority of such complications were the result of embolism from the operative field (5). This conclusion was based on the following reasoning:

1 The clinical course of a majority of the so-called postoperative or ether pneumonias was rarely so severe, nor the duration long enough,

FIG 4—Dog Y 16 Three days after embolism. Note beginning consolidation.

do not diminish the morbidity percentage of these complications nor is it greatly affected when the anesthesia is in the most expert hands. Indeed, it would seem reasonable to state that if aspiration always occurs it for that very reason cannot be the chief etiological agent, otherwise a far larger percentage of patients would present the picture of some one of the pulmonary complications.

Postoperative lung abscess occurs frequently following operation within the bucco-pharyngeal

cavity, and, as tonsillectomy is by far the most common operation in this field, lung abscess has in a general way become attached to this particular operation. Certainly it is our laryngological colleagues (10, 11, 12, 13, 14) who write about it and discuss it most frequently. However, a careful analysis of the facts shows that the fre-

FIG 5—Dog Y 16 Five days after embolism. The entire lobe is consolidated

quency of lung abscess after tonsillectomy is no higher than with other operations in a septic field*. It is merely that the great number of tonsil operations performed yearly affords an opportunity for more of these cases to appear in relation to tonsillectomy than with other operations. Obviously in either the recumbent or

FIG 6—Dog Y 16 Eight days after embolism. Great extension process

the lying position the opportunity for aspiration is present. Indeed it seems as if it were so obvious that no one thought to look further for the cause of this disastrous complication.

*We have been able to collect 1908 cases of lung abscess in the literature 29.6 per cent of which are postoperative. 14.6 per cent of the total followed tonsillectomy.

This same attitude of mind existed in the early days of ether anesthesia, as regards the operations of general surgery. Preceding ether, no one thought of pulmonary complications since the danger of hemorrhage and sepsis so outweighed all other risks. With the advent of inhalation anesthetics and finally of antiseptics and asepsis, surgical technique so improved that the lesser evils of operations began to show up. The anesthetic, as the only new agent added to surgery and as a drug absorbed directly by the lung, was naturally blamed for all pulmonary complications. In 1879 Von Anrep (15) discovered and developed cocaine as a local anesthetic. This slowly came into use but when it did so, the

FIG 7—Dog Y 16 Cut surface left lower lobe showing extensive necrosis with cavity formation, also point of rupture into pleural cavity

more studious surgeons came to see that post-operative pulmonary complications still occurred. So from the simple historical perspective, we have some reason for thinking that the aspiration-irritation theory cannot explain all these complications.

This same perspective may be used in regard to tonsil operations, for enough statistics of lung abscess as a sequel to operations upon the tonsils under local anesthesia are now at our command to allow us the same doubts as to the rationality of the aspiration-irritation theory in this field as well (12, 16).

Curiously the problem has been attacked experimentally almost solely from the aspiration point of view. Innumerable investigators have instilled great varieties of bacteria with and without foreign bodies, of both organic and inorganic matter, into the lung via the trachea (17, 1, 18, 19). None have succeeded in creating typical, slowly developing lung abscesses with a high de-

FIG 8—Dog Y 20 Roentgenogram immediately after embolism Lead filing demonstrates lodgment of embolus in left lobe.

gree of uniformity and regularity We felt that lung abscess presented us with an opportunity to bring more evidence to our own convictions that embolism was the chief method by which postoperative pulmonary complications were initiated, since, could we create lung abscess by such a simple method as freeing an infected embolus into the venous circuit, we would be able by means of the X-ray and surgery to study its further development This opportunity is not afforded when one attempts to study experimentally the other forms of postoperative lung complications, where an elucidation of complaints and the study of clinical symptoms depends so much on our conversational ability

In order that our investigations might be fully controlled and to avoid criticism from those still holding that the aspiration of infected material might be the source of lung abscess, we first attempted to produce lung abscess by the introduction of infected materials into the air passages Using a small bronchoscope, a great variety of materials infected with many kinds of organisms were introduced as deeply in the bronchial tree as possible The materials used included infected tonsils, carious teeth, peanut kernels, bits of metal, etc In fifteen experiments not a single abscess was produced, though some of the animals died within three days of a gross infection which had perforated the bronchus at a point injured by the bronchoscope Histological study of the specimens showed no evidence of pulmonary infection

THE PRODUCTION OF LUNG ABSCESS BY INFECTED EMBOLI

We then devised a method for freeing small infected emboli in the venous circuit. In order that the infected material be brought to the field intact, it had to be enclosed in some sort of a capsule that would, once lodgment of the embolus

had occurred, free the organisms for their further development In order to more closely simulate actual conditions, the substance holding the organisms should be inert, in fact we should try to simulate an infected clot Further, we should add to our embolus a small piece of metal that would show in the X-ray films in order to locate the site of the lodgment of the embolus preceding the development of a consolidated area We used a small bit of lead for this latter purpose, and this served not only as a guide to the original lodgment site, but, as the consolidated area broke down and liquefied, the metal shifted in its position in the clear central zone of the abscess, as shown by the X-ray films, and gave as a very secure demonstration of cavity formation This piece of metal was coated with paraffin to render it inert Many capsules and substances that would carry bacteria, also infected meat, bits of infected tonsils, etc., were used in our experiments, but we finally adopted as a standard embolus an excised piece of femoral vein, tied off at each end and filled with bacterial emulsion (Fig 1) For bacteria we have used staphylococcus aureus, *Bacillus coli*, pneumococcus and streptococcus anhemolyticus Since the jugular vein in a dog is large and easily accessible, the embolus was usually placed in this vein, but exactly similar effects were produced when in a few experiments the embolus was inserted into the femoral vein

The Method—The vein is cut down upon under either general or local anesthesia, isolated, pulled into the wound by two sutures, opened between the sutures after temporary clamps have been placed above and below, a glass cannula is inserted into the open vein, the embolus is placed in the cannula and then washed into the vein with salt solution from an attached glass syringe (Fig 2) The vein is then sutured and the embolus allowed to escape towards the heart

Immediate X-ray films demonstrate the place of lodgment of the embolus and daily subsequent

FIG 9—Dog Y 20 Two days after embolism Note beginning infiltration

films picture the development first of the consolidated area and the later of the cavity formation within this area. In one hundred experiments sixty per cent of the emboli lodged in the left lower lobe, undoubtedly because of the straighter course and greater volume of blood within the vessel going to this lobe. The same reasons for distribution hold in human cases where the greater percentage of abscesses are found in the right lower lobe.

The following experiments demonstrate the method and its results.

Experiment I—Dog Y 16, brown and white, long haired female mongrel, weighing 102 kg,

FIG 10—Dog Y 20 Six days after embolism. Note increase in consolidation and cavity formation. The lead filings have dropped to lie in the bottom of the rarefied area.

Sept 18, 1925 was given one-fourth grain morphin. Under ether anesthesia, the right jugular vein was prepared in the usual manner. A piece of human tonsil additionally infected with a loopful of staphylococcus aureus from an agar slant and with paraffinized lead filings attached was placed into the glass cannula, the cannula was inserted into the vein, and the embolus was forced onward with salt solution. The vein was sutured with silk and the skin was closed in the usual manner. A roentgenogram of the chest revealed the foreign body in the left lower lobe (Fig 3).

Sept 21, 1925—The animal appeared sick, refused both food and water. When first seen in the morning, blood was found in the cage, and examination revealed old blood in both nostrils. X-ray revealed a beginning infiltration in the left lower lobe (Fig 4).

Sept 23, 1925—The animal continued ill and would not eat. The entire left base cast a very dense shadow in the roentgenogram (Fig 5).

Sept 26, 1925—A roentgenogram of the chest (Fig 6) showed a very dense shadow occupying the entire lower half of the left chest. No fluid

level nor pneumothorax could be demonstrated. The animal died at noon.

Necropsy—Both pleural cavities contained a large amount of dark bloody fluid. There were no pleural adhesions. A large blood clot was present in the left pleural sinus. The entire left lower lobe was large and firm. In the lower part of the lobe an abscess cavity about the size of a walnut was found to have ruptured into the pleural cavity (Fig 7). The upper left lobe showed almost complete atelectasis while the lobes on the right were air-containing and apparently normal. Microscopically, a section taken through the abscess wall showed an acute diffuse inflammation of the neighboring lung tissue. The infiltrating cells were mostly leucocytes. The inner wall of the abscess was composed of fibrin and necrotic tissue.

Experiment II—Dog Y 20, long haired, black female mongrel, weighing 106 kg, Oct 3, 1925, was given one-fourth grain morphin. Under ether anesthesia a segment from the right femoral vein was removed, inoculated with *Bacillus coli* and staphylococcus aureus and introduced into the left jugular vein. The vessel was sutured with silk, and both skin incisions were approximated with a subcuticular stitch of silk. A roentgenogram of the chest localized the foreign body in the left lower lobe (Fig 8).

Oct 5, 1925—A roentgenogram of the chest showed considerable infiltration about the foreign body in the left lower lobe (Fig 9).

Oct 7, 1925—A large circumscribed area of density was present in the left lower lobe.

FIG 11—Dog Y 20 Cut surface left lower lobe removed by lobectomy showing abscess cavity with necrotic walls. There is a wide zone of tissue reaction which histologically consisted chiefly of acute diffuse inflammation.

Oct 9, 1925—A roentgenogram showed a large cavity in the center of the area of density (Fig 10). The lead filing had dropped to the bottom of the cavity. The lobe was removed by operation. The left lower lobe revealed an indurated mass in the center of the lobe. Fluctuation within the mass could be palpated. On sectioning, an abscess cavity about the size of a walnut was encountered containing necrotic tissue and pus (Fig 11). Cultures taken from the pus revealed staphylococcus and *Bacillus coli*. Microscopically, a section taken through the abscess wall showed the inner wall of the cavity to be made up of

Fig 8—Dog Y 20 Roentgenogram immediately after embolism. Lead filing demonstrates lodgment of embolus in left lobe.

gree of uniformity and regularity. We felt that lung abscess presented us with an opportunity to bring more evidence to our own convictions that embolism was the chief method by which postoperative pulmonary complications were initiated, since, could we create lung abscess by such a simple method as freeing an infected embolus into the venous circuit, we would be able by means of the X-ray and surgery to study its further development. This opportunity is not afforded when one attempts to study experimentally the other forms of postoperative lung complications, where an elucidation of complaints and the study of clinical symptoms depends so much on our conversational ability.

In order that our investigations might be fully controlled and to avoid criticism from those still holding that the aspiration of infected material might be the source of lung abscess, we first attempted to produce lung abscess by the introduction of infected materials into the air passages. Using a small bronchoscope, a great variety of materials infected with many kinds of organisms were introduced as deeply in the bronchial tree as possible. The materials used included infected tonsils, carious teeth, peanut kernels, bits of metal, etc. In fifteen experiments not a single abscess was produced, though some of the animals died within three days of a gross infection which had perforated the bronchus at a point injured by the bronchoscope. Histological study of the specimens showed no evidence of pulmonary infection.

THE PRODUCTION OF LUNG ABSCESS BY INFECTED EMBOLI

We then devised a method for freeing small infected emboli in the venous circuit. In order that the infected material be brought to the field intact, it had to be enclosed in some sort of a capsule that would, once lodgment of the embolus

had occurred, free the organisms for their further development. In order to more closely simulate actual conditions, the substance holding the organisms should be inert, in fact we should try to simulate an infected clot. Further, we should add to our embolus a small piece of metal that would show in the X-ray films in order to locate the site of the lodgment of the embolus preceding the development of a consolidated area. We used a small bit of lead for this latter purpose, and this served not only as a guide to the original lodgment site, but, as the consolidated area broke down and liquefied, the metal shifted in its position in the clear central zone of the abscess, as shown by the X-ray films, and gave as a very secure demonstration of cavity formation. This piece of metal was coated with paraffin to render it inert. Many capsules and substances that would carry bacteria, also infected meat, bits of infected tonsils, etc., were used in our experiments, but we finally adopted as a standard embolus an excised piece of femoral vein, tied off at each end and filled with bacterial emulsion (Fig 1). For bacteria we have used staphylococcus aureus, *Bacillus coli*, pneumococcus and streptococcus anhemolyticus. Since the jugular vein in a dog is large and easily accessible, the embolus was usually placed in this vein, but exactly similar effects were produced when in a few experiments the embolus was inserted into the femoral vein.

The Method—The vein is cut down upon under either general or local anesthesia, isolated, pulled into the wound by two sutures, opened between the sutures after temporary clamps have been placed above and below, a glass cannula is inserted into the open vein, the embolus is placed in the cannula and then washed into the vein with salt solution from an attached glass syringe (Fig 2). The vein is then sutured and the embolus allowed to escape towards the heart.

Immediate X-ray films demonstrate the place of lodgment of the embolus and daily subsequent

Fig 9—Dog Y 20 Two days after embolism. Note beginning infiltration.

FIG 15—Dog Y 21 Twenty-eight days after embolism There is still a faint and restricted zone of consolidation and the lead filing seems to be in a small cavity

of the tissues in the lung, and the presence of other organisms already present but of insufficient virulence to establish disease by themselves. Also the question of the importance of the condition of local infraction is brought up. The resultant circulatory changes may be of considerable importance.

These experiments would seem to demonstrate that at least a certain number of postoperative lung abscesses may be due to infected emboli from the operative field. They further strengthen our view that most postoperative pulmonary complications may have a similar etiology. If this is so the lesson is for the surgeon, not for the anesthetist. Such complications can only be reduced, they can, probably, never be entirely avoided. Gentle handling of tissues, the most meticulous surgical technique, perfect hemostasis and the greatest asepsis possible under the condition imposed by the field of operation will surely reduce not only the morbidity from lung abscess but from all other postoperative pulmonary complications. We hope that this possible explanation of postoperative lung abscess will have as much influence in lowering the disability from this disease as the great amount of effort already put into methods of therapy.

FIG 16—Dog Y 21 Cut section through left lower lobe, removed at operation, shows a healed fibrous scar without cavity or evidence of infection. The piece of metal is firmly embedded in dense connective tissue.

fibrin and necrotic tissue. The adjoining lung tissue was densely infiltrated with leucocytes. There was considerable recent hemorrhage. Histologically, the picture was one of acute diffuse inflammation.

Experiment III—Dog Y 21, shepherd, male, weighing 15 kg, Oct 7, 1925, was given one-fourth grain morphin. Under ether anesthesia a segment from the right femoral vein was removed, inoculated with cultures of *Bacillus coli* and introduced into the left jugular vein. A roentgenogram of the chest localized the foreign body in the left lower lobe (Fig 12).

Oct 8, 1925—An area of cloudiness could be seen about the foreign body (Fig 13).

Oct 12, 1925—The area of density was larger in size and a distinct cavity was visible (Fig 14).

Nov 3, 1925—Subsequent roentgenograms (Fig 15) of the chest revealed a persistence of the cavity. The animal seemed normal in every way, good appetite, active, no cough, no fever.

Nov 9, 1925—The left lower lobe was removed by operation. The specimen showed a healed

abscess. A combination of organisms as stated above seems most useful.

There also appears to be some importance at-

FIG 13—Dog Y 21 Twenty-four hours after embolism. There is already considerable clouding of the field about the piece of metal.

FIG 12—Dog Y 21 Roentgenogram immediately after embolism. Note lodgment lead filing in left lower lobe.

fibrotic lesion (Fig 16). Microscopic sections were not taken.

These are merely typical experiments. They can be repeated at will. Using this method and with the same bacteria we have had one hundred per cent successful results. We have found that many factors play an important role. Thus, the type of organism is of the greatest importance, and, though we have been able to produce typical abscesses with *Bacillus coli*, streptococcus an-hemolyticus and staphylococcus aureus alone, we have also had several failures, the animals recovering without ever showing any signs of abscess. *Bacillus coli* seems to be the most useful of all organisms for this purpose in the dog. Pneumococci alone—even virulent strains recovered from fatal human cases—have not sufficed to produce

tached to the physical properties of the embolus. Thus, with infected tonsils, infected meat, etc., the lesion frequently kills the animal soon after the production of the abscess. It may be that enclosing the infected material in a segment of vein allows the production of a high local resistance and walling off process before the organisms are actually freed into the tissues in great number. Experiments conducted in which a simple infected clot was released resulted much the same as when infected tonsillar tissue was used. Just what are the physical and immunological conditions in human cases that establish the favorable local condition for a lung abscess is still unknown, but it may well depend upon

FIG 14—Dog Y 21 Five days after embolism. Note considerable area of consolidation with cavity formation.

several factors such as the size of the clot, the amount of infection it carries, the local resistance

locate any lesion in the lens by observing these lamellar or discontinuity zones

Gross changes in the anterior capsule are evident to the superficial observer but minute lesions are only found with the slitlamp. If an isolated area has pigmented spots on its surface, it is presumptive evidence that the opacity extends to the capsule. If there are fibers of pupillary membrane attached to the opacity, we consider the cataract congenital. The pupillary membrane fibers always come from the shelf of the iris, never from the pupillary margin. A congenital cataract may show reduplication of the opacity in several layers, frequently concentric but often with ballooning extensions. Such cataracts resemble spools in shape. They are easily distinguished from shadows by changing the angle of illumination and observation. True thickening of the capsule is rare.

So-called posterior capsular opacities are easily differentiated from posterior cortical changes by exact focusing on the capsule. These are remnants of the hyaloid and are properly designated posterior hyaloidea capsularae. They all vary in form, thickness and end extensions. Detected in the usual ophthalmoscopic examination as a black dot generally to the nasal side of posterior pole of the lens, it assumes a new form under the slitlamp.

White dots, specks or fibrils may be scattered throughout the entire lens. When few and irregularly placed they are, as far as we know, without pathological significance. They are found in the majority of lenses. When, however, these dots are arranged in concentric rings, they are pathological. Another frequently observed form of isolated opacities are the finger-like projections of coronar cataract, which may be associated with other opacities.

We have now reconstructed the lens by superimposing and combining the layers of opacities which we have found in a large series of cases. We know that an opacity of the lens may follow these definite and distinctive zones.

A lamellar or zonular cataract is an example of a common form of regular cataract. Dense lamellae may be present, the faintest dot may show the location or there may be any degree of opacification between these extremes. Extending into more peripheral layers than the ones of greatest opacity are irregular hooks or arcs of white fibers called riders. We may have small riders without lamellar suggestion or both, layer cloud and hook may be manifest.

The opacities so far described have followed a regular order of distribution. There is a large group in which the opaque areas are irregularly placed. These include upper qua-

drant defects, isolated fibers, twisted white cords and many other types.

The color of the cataract depends upon the amount of enclosed pigment, on the thickness of the opacity and its position in the lens. Thin opacities sometimes have a bluish tinge, denser and deeper ones a gray-color. Deep cortical nuclear changes are always yellowish brown. An iridescent sheen may be seen. This is common in the posterior cortical changes but less frequent in the anterior ones.

Most of the slowly advancing and rapidly progressive cataracts can be separated pathologically and clinically. This is the particular phase of the subject to which especial attention is drawn. Slowly advancing opacities may be either in the periphery or in the center of the lens. The most common form, when seen with the ophthalmoscope, appears as black streaks with wavy outline and when examined under the slitlamp looks like fissures in clear ice, such as the iceman makes with his axe when he divides the cakes into small pieces. These opacities always involve many layers of lens fibers and may advance so slowly that it is impossible to observe any progress from one year to the next. The central cataract usually corresponds to the size of the lens at birth, appears yellow and is seen more easily with the ophthalmoscope than with the slitlamp. Either type may remain unchanged for years. Other cases show a little increase in the depth and width of the fissure, also an increase in number. These forms should never be confused with senile or progressive cataract.

The question is just what constitutes a progressive cataract. The basic change in the lens is an imbibition of fluid by the lens fibers showing first when seen with the slitlamp as a black cleft or clefts most often extending from the periphery of the lens. As the disease progresses, these crevices become filled with broken lens fibers, cell debris and more or less spherical Morganian bodies. The boundaries of the clefts later become opaque. The destruction of the lens fibers continues. Fluid is first seen as a single round or oval drop but as the drops increase in number and size they coalesce and form a distinct oil-like layer between the lens and its capsule. After a time the fluid begins to absorb. The opacity then rapidly becomes greater. Later so much of the fluid is absorbed that the lens returns to its normal thickness and the anterior chamber to normal depth. This is the most favorable time for expressing the lens from its capsule. If operation is delayed, the liquefaction of the lens fibers continues and a milky fluid consisting of lens debris and Morganian bodies fills the capsules except for the brown nucleus.

When the lens capsule is opened, as for the absorption of a zonular cataract, it is possible

THE MODERN CONCEPTION OF CATARACTS

By ARTHUR J BEDELL, M D, ALBANY, N Y

CATARACT has been known for centuries. The term is found in medical history as early as 2250 B C. It is probable that operations similar to those in present use were in vogue 500 years before Christ. The Pompeian collection contains instruments similar to those of today. The late Dr S Lewis Ziegler recently completed a most instructive thesis on the historical side of cataract to which all are directed for authentic information.

We wish to speak of the changes that have taken place in our knowledge of cataracts and especially to differentiate between three types, stationary, slowly advancing and progressive. Traumatic changes will not be discussed.

As late as 1706 a cataract was supposed to be a pellicle inside of the capsule. This was disproved by Daviel. Later Morgagni described the lens changes which are linked with his name. The lens is usually defined as consisting of cortex and nucleus, although in Von Ammon's atlas Fig 1 published in 1841 there is a

FIG 1—A reproduction from Table XI, Fig XXXV, *Klinische Darstellungen der Krankheiten und Bildungsfehler des menschlichen Auges der Augenlider und der Thränenwerkzeuge nach eigenen Beobachtungen und Untersuchungen herausgegeben von Von Ammon*, published in 1841.

drawing of a lens showing many layers of opacification. Apparently this picture was not commented upon. A few years ago, Vogt using the slitlamp found that the lens consisted of many divisions. Fortunately, the improved methods of routine examination make it possible for us to see and recognize that these divisions are normal and can be demonstrated in almost every lens.

We can reconstruct a lens by noting the lines of discontinuity or by combining the opacities found in a large series of cases. To do this, we must have a simple and yet an accurate chart for recording lens changes. Fig 2 right shows the front view of the lens, and left, Fig 3 the

profile with the phantom lines suggesting the recognized sub-divisions. Both must be used in recording every case. It is also essential to note the size of the pupil. This diagram shows why

FIG 2—LEFT—Profile view of the lens anterior surface to the left. RIGHT—The recognized demonstrable lens divisions.

full dilatation of the pupil is obligatory, if we are to know the condition of the lens. No record of a cataract or its progress is complete without such notations.

On this chart we record a single white spot, a few white dots or a continuous sheet in the mathematical center of the lens. Passing forward and backward, the curved lamellar surfaces of the central interspace are suggested by scattered specks or completely outlined by a white layer, anterior axial embryonal cataract. This is our first zone of discontinuity and is so determined even when the lens is perfectly clear. Advancing or receding still farther, we come to the embryonal nucleus margin which is easily distinguished because of two outstanding features, an anterior upright Y and a posterior inverted Y. These Y's are on the surface of the lens as it exists at birth. The Y may present an infinite variety of forms, at times a mere suggestion of its shape is indicated by a nebulous white haze. The extensions of the Y may be short or even absent. At other times, the arms are elongated, frequently thickened and occasionally dense white. Sometimes they are so thick and so white that they are visible to the naked eye.

New lens fibers are being constantly added to the embryonal nucleus, finally showing a new zone, the adult nucleus at about the time of puberty. The surface of this presents many distinctive elevations, knobs and ridges. Between the capsule and the adult nucleus fibers continue to form until death. We are able to

every cataract All the scientific and clinical methods at our command must be used to determine the diagnosis of every case If this is done, each type will be understood and a correct prognosis can be given the patient This

will lead to a saner, truer and more professional contact with the patient, who in turn will be able to live his life without undue or unwarranted anxiety

"THE MODERN CONCEPTION OF CATARACTS"

By MARTIN COHEN, M.D.,

A Discussion of the Paper by Dr Arthur J Bedell

THE development of cataract cannot be adequately understood from changes in the lens alone The humors of the eye play an important part in nutrition of the lens and in maintaining its normal composition Before studying the etiology or relief of any particular eye disease, we have undertaken the study of the chemical composition of the humors and lenses of normal animal eyes on a comprehensive scale Before determining how these humors arise and the relation they bear to the blood, it is essential to know their composition The results of those analytical studies on the ocular fluids have already been published It is not necessary to state them now, except to mention that these results show that there is an active metabolism going on within the eye The vitreous fluid is very similar in composition to the cerebro-spinal fluid, but the aqueous appears variable It appears warranted to conclude from our studies that the aqueous humor represents the accumulation of the waste products from the eye metabolism

Our work on the normal lens is far from being complete, however, several significant facts have been demonstrated The solids of the lens are almost wholly protein Morner has demonstrated four proteins present, an albuminoid, alpha and beta crystalline and an albumin Probably the best work reported in the literature demonstrates that the chief variation between normal and cataractous, not traumatic lenses, is in the character of the proteins (Jess) In the matured cataract, the crystallines have disappeared, in immatured the amount present is diminished The method of preventing cataracts, or of arresting their development by the use of lens antigen or vaccine administration is based, I believe, on a false assumption This antigen is an extract of normal lens of animals, and is injected into human subjects with incipient cataract, on the assumption that there is no difference between the composition of the normal and the cataractous lens This assumption is ob-

viously incorrect, in view of reliable reports in the literature It is difficult to see how the use of this antigen will restore the alpha and beta crystalline to the cataractous lens, any more than any other non-specific protein There is a marked difference between the inorganic constituents of the eye humors and the lens The humors are largely physiological salt solutions, but the lens contains but a very small amount of inorganic constituents These, however, change with age, and may also change with the development of cataract Cholesterol likewise increases in concentration in the lens with increasing age, and it has been asserted by some that cholesterol is more abundant in the cataractous than in the normal lens

Goldschmidt has shown that the lens possesses an autooxidation system more efficient than any other tissue of the body Such a system is essential for the metabolism of the lens and is due to the presence in it of glutathione In cataractous lens this glutathione activity is greatly diminished or absent This has been confirmed by work in England on "glass blowers' cataract" Such observations demonstrate that these changes involved in the production of cataract are similar to changes seen in any tissue in the death of that tissue However, these are only effects Further investigations into the biochemistry of the humors and of the lens of the eye are essential to demonstrate the causes, and to indicate the possible rationale of prevention For that reason we have attempted to study the biochemistry and metabolism of the eye as a whole Biochemists and clinicians are beginning to realize more and more that physico-chemical phenomena play as important a part in regulating the metabolism of the body as quantitative relations It will be possible to approach the problem of cataract intelligently only when our knowledge of the biochemistry of the eye and of the physico-chemical phenomena concerned in its metabolism is more complete

to see the lens fibers swell and become detached from their surroundings. Later the individual fibers become fractured and still later swollen, waved fibers, broken cells and granular white bodies are present. By analogy, we may conclude that the lens undergoes similar but less rapid changes in progressive cataracts.

Four types of senile cataract are clinically differentiated, adult nuclear, diffuse, central and posterior cortical. The adult nuclear opacities are seen as projecting spires or an irregular smudge and begin most often in the inferior nasal quadrant. These involve both anterior and posterior layers of the senile nucleus and are often partly obscured by thin, overlying concentric lines of increased density.

Diffuse opacities are scattered throughout the lens and are usually densest in the equatorial periphery. In concentric layers of granules, specks, dots, dashes and fibrils they advance into the pupillary area.

The center of the lens may become opaque.

There are three forms of posterior cortical involvement which must be considered at this stage of our discussion, because two of them are always progressive cataracts and the third may be. The two which are always progressive are complicate cataract and the saucer type. To distinguish between them is not difficult. In the saucer there is a thin opacity which looks somewhat like a dark gray sheet with scattered black perforations resembling pumice stone in appearance. Complicate cataract consists of a mass of rounded, projecting gray spheres, densest at the posterior pole and extending laterally and centrally. Another allied form of posterior cortical cataract is that which is seen in many cases of advanced retinitis pigmentosa. This is characterized by innumerable small globules which seem to form in the beginning a rather thin layer close to the posterior capsule. The same massing of spheres has also been seen in the anterior cortical layers after iridectomy. The rosette or fourth form is a thin opacity surrounding the sutures of the posterior portion of the lens. This may be the result of contusion and is the only type of posterior involvement which may show a tendency to resorption.

All forms may be combined in the same cataract, adult nuclear and posterior cortical changes are most often associated.

Because of the limitation of time, it is impossible to discuss traumatic cataract, details of the lens margin including congenital notching and zonular fiber attachments or dislocation of the lens.

Cataract is described as an opacity of the lens or its capsule, but we as ophthalmologists must differentiate types for clinical purposes. We should not use the old term "incipient" cataract, which is neither descriptive nor com-

prehensive, for it is used to embrace not only the slowly advancing lens changes but also the rapidly progressive ones. The modern conception of a cataract should be opacities laid down at the development of particular portions of the lens, those which begin in middle adult life but never totally obscure the sight and finally progressive opacities in which the clouding of the lens is rapid.

Reference to the pathologic processes proves that the increased fluid content of the lens may be lessened and the patient have better vision but that the disease process is still progressing and later the vision will be reduced again. It is a fallacy, therefore, to use vision as a measure of improvement, for the reason that all senile cataracts go through certain stages, which certainly in the vast majority of cases are not influenced by any drug or any external measure, unless it is refraction. Thousands of cataracts remain almost stationary for years, without any treatment. Many more thousands progress to maturity in spite of all that is done. Only the exact clinical observation of the lens, and this of course includes careful slitlamp examination made by a competent observer, must be the basis for deductions regarding the value of any form of treatment. The mere expression, "examination by slitlamp" means nothing.

So many patients have been exploited and so many cures have been foisted upon the public that this particular method of sub-division must, I believe, be presented to the public. They must be made to understand that a senile or progressive cataract is a condition which seemingly cannot be controlled and should be likened to advancing age, senility. They must also appreciate that senility is a relative term, and individual in its application. A patient is entitled to know that an opacity of the lens may progress to a certain point and then stop, without any change in his surroundings or general health. He should be told that the change is similar to the graying of hair, which is frequently an expression of hereditary tendencies, and may appear at any age. This is not said in a frivolous way, but is intended to emphasize the fact that if a patient has a senile cataract no one to my mind is warranted in saying that it can be cured or that its progress can be checked by local treatment. As yet no clinician has definitely described the microscopic changes that have taken place in a lens as a result of local therapy.

In conclusion, as the word cataract suggests to the laity impending blindness, we urge the restriction of the use of the term and especially ask that modifying adjectives be used that will definitely describe the particular form of cataract such as congenital, stationary, slowly advancing or senile progressive. We also ask for a more careful physical examination of

part of the world, since so many natural foods contain it and suitable modifications in the food supply will prevent any shortage of it. There is, however, an alcoholic extract of rice polishings, known as tiki-tiki, which for some years has found application in therapy in infantile beri-beri in the Philippines.

Vitamin C deficiency leads to the development of scurvy. The provision in the diet of any one of a list of common fruits or vegetables in the fresh condition supplies this vitamin. Attention to the diet with respect to its antiscorbutic value is now universally given, especially in the feeding of infants. It may be well to state that although orange juice and tomato juice have been the sources of vitamin C generally recommended, the juice of turnips, cabbage, carrots or potatoes appears to be entirely appropriate for administration to infants. These are to be recommended in places where citrus fruits or tomatoes are not available.

In rickets there is a disturbance of calcium and phosphorus metabolism which causes the well known abnormalities of bone growth. The vitamin D in some way effectively directs the processes of calcification in the growing bones when the disease exists, causing recovery. It appears that infants born with a poor physical inheritance are especially susceptible to rickets and may develop the disease when the diet is satisfactorily constituted for children with better physical inheritance. It has been demonstrated that young animals of certain species, e. g., the rat, develop rickets when fed diets which are unfavorably constituted in that they contain too little calcium and a disproportionately large amount of phosphorus or too little phosphorus and a disproportionately large amount of calcium, and are deficient in vitamin D. Babies develop rickets on diets which would never cause the disease in little rats. Cod liver oil, because of its richness in vitamin D, is very effective in curing the disease in both species. The difference in the susceptibility of human infants and young animals seems to be due to feeble powers of assimilation of the former. The administration of cod liver oil is an effective measure of insuring that rickets will not develop.

There is no unanimity of opinion concerning the proper dosage of cod liver oil for infants. We find that young rats cannot tolerate very liberal amounts (e. g. above 6 to 7 per cent of the diet) without injury. Anyone who has taken the oil knows the tendency to disturbances of digestion which it causes. Experiments on animals show that relatively small amounts exert a profound influence in bringing about the healing of the rickets lesion. It seems logical to believe that many people are now giving children considerably more cod liver oil than is necessary.

One of the most interesting and important advances in research on nutrition in recent years is the demonstration that sunlight and especially ultra violet light has a pronounced effect in promoting physical well-being. Irradiation with ultra violet light produces effects which are comparable to those produced by taking cod liver oil. It has been shown by Hess that irradiation of cholesterol causes it to acquire antirachitic properties. There is reason to believe that cod liver oil may owe its therapeutic effects to the presence in it of the active form of cholesterol. The short rays of light are highly active chemically. It is easy to do harm by too great exposure to these rays especially when the skin has not been well tanned by cautious and progressive exposure.

It will be seen from what has been said that in certain restricted areas of the world each of the vitamins is likely to be deficient in the food supply. In many regions, especially in industrial sections where the food supply is entirely derived from retail stores, there may be multiple vitamin deficiency to an extent that the optimal intake of more than one or two of them is seldom reached. The farm, the garden, or the fresh vegetable market, together with the milk supply, afford articles which if secured would improve the dietary and make the difference between a dietary regimen which will support well-being, as contrasted with the typical dietary of white bread, meat, potatoes and sugar, syrup or molasses, which is inadequate and may result in gradual impairment of vitality and health.

The vitamin E has been shown to play a role in the nutrition of the rat which is very different from that of any other vitamin. This substance, according to Evans, is not necessary for growth nor health, and without it oogenesis and spermatogenesis take place normally but when it is absent in the food supply of the mother it is not possible for the young to survive much beyond the middle of the normal gestation period. The distribution of this vitamin in relative abundance in whole grains, in certain vegetable oils, meats and green vegetables, would lead one to suspect that human sterility is very seldom if ever to be referred to deprivation of this substance. It has, as yet, not found any place in therapy.

Students of public health problems have repeatedly emphasized that the program thus far followed has been effective mainly in two directions. It has greatly decreased the death rate from certain transmissible diseases against which the public can be protected by vaccination, quarantine, mosquito, hookworm and yellow fever control, pure water, pure milk, etc. It has been eminently successful in preventing infant mortality through safeguarding the milk.

THE RELATION OF VITAMINS TO DISEASE*

By E M McCOLLUM, Ph D, BALTIMORE, M D

SINCE the fundamental observation of Eijkman in 1897 that beri-beri is the result of limiting the diet almost exclusively to polished rice, and that there is something in the outer layers (germ) which is capable, when administered in very small amount, of preventing or of relieving the symptoms of the disease, progress in research on the class of nutrients of which we require but apparently insignificant amounts has reached the point where we now recognize the existence of at least five, and probably six, vitamins. These are known as vitamins A, B, C, D, E, and P-P.

The outstanding pathological effects which result from deprivation of an individual for a single one of these when it is confined to a diet which is otherwise complete, make it clear that there may arise, and frequently has arisen, in human experience disease which may be attributed to specific vitamin starvation.

Thus, deficiency of vitamin A results inevitably in the appearance of xerophthalmia. The lacrymal glands lose their functional capacity, resulting in failure of tear secretion. The eyeballs become dry and are overgrown by microorganisms. Ulcers form on the cornea, which finally perforate the eyeball, resulting in extrusion of the lens. Administration of suitable amounts of any fat containing the vitamin A results in a spectacular return of these structures to a healthy condition, in some cases even after the sight is destroyed. The salivary glands are likewise affected. They also cease to function. Besides the eye changes there is much evidence that deprivation of vitamin A affects specifically the epithelial tissues. It has been asserted that it results in a marked reduction of blood platelets, and in a peculiar disturbance of ovarian function in which the ovaries extrude one, two or three ova at frequent intervals instead of a much larger number on a cycle of approximately 96 hours.

There is also much evidence (Daniels) that vitamin A deficiency leads to increased susceptibility to infection. The nasal and aural cavities become filled with a purulent discharge. Osborne and Mendel have attributed the formation of urinary calculi on low vitamin A diets to alkalinity of the urine as a result of bacterial decomposition. This view postulates a weakening of the defensive mechanism against bacterial invasion.

There are satisfactory reasons for believing that the disease known in Japan as "hikan" is primarily a vitamin A deficiency disease (Mori). Vitamin A is abundant in cod liver oil and other fish oils, in butter fat, as well as

in a number of leafy vegetables, and is found in smaller amounts in many natural foodstuffs. Although xerophthalmia occurs rarely in America it is highly probable that hemeralopia and nyctalopia have not infrequently been encountered as the result of faulty diet in mining and lumber camps, and among the inhabitants of Newfoundland and Labrador.

Eijkman described the symptoms of polyneuritis resulting from what is now known as vitamin B starvation. There is at present much reason to believe that what has been known for several years as vitamin B is in reality two or more substances. One of these is an antineuritic substance which prevents or relieves polyneuritis, the other being a substance which is regarded by Goldberger as probably the etiological agent, or a contributing factor in the causation of pellagra. Both of these substances are found together in the natural foods thus far studied. Smith and Hendrick and Goldberger, et al have shown that in yeast the antineuritic substance is readily destroyed by heating in an autoclave, whereas the anti-pellagra substance, designated by Goldberger as P-P, is stable.

It is impossible to segregate at this time the pathological changes which result from a deficiency of each of these vitamins. The multiple neuritis results from starvation for the heat-labile one, and apparently the primary lesions of pellagra from deprivation of the heatstable component.

When the animals are fed a diet of polished rice there is, among other deficiencies, a lack of the antineuritic substance. McCarrison has discussed the changes seen in vitamin B starvation under four divisions. In the first are chronic undernutrition, resulting in atrophy of the musculature and glandular structures. This results in impairment of digestion and assimilation. Following these changes there is a partial loss of mass of the endocrine organs except the adrenals, which undergo hypertrophy, and lastly a pathological state of the nervous tissues. He attributes these phenomena to a specific starvation of the cell nuclei, but has not yet presented very good evidence in support of this view. It would be out of place here to recite the details of the several speculations which have been set forth to explain the mechanism of the action of vitamin B. Its probable multiple nature was suggested a year ago by Laird, working in the author's laboratory, and the studies of Smith and Hendrick and Goldberger, and his coworkers, strengthen this view. It will suffice to say that a deficiency in the human diet of the nutrient fraction called vitamin B is inexcusable in any

APPENDICITIS IN EARLY LIFE*

By EDWARD WADSWORTH PETERSON, M.D., F.A.C.S., NEW YORK

MUCH has been written about appendicitis in childhood, much more should be written on this subject, for it is the most frequent and the most important surgical affection of the abdomen in early life. Practically all writers have emphasized the following points: the relative rarity of the disease under five years of age, the difficulty of diagnosis, owing to the insidious onset and the obscure clinical picture, the tendency toward early perforation, with rapid spread of inflammation and overwhelming toxemia, and the high mortality in childhood, especially in the first half decade of life.

In my opinion appendicitis is not at all uncommon under five years of age. I do agree, however, that it is rarely recognized at this period, and, under two years of age it is usually overlooked entirely in all but the worst cases. I am willing to grant that in certain cases the onset is insidious, the clinical picture obscure and the physical examination absolutely misleading, but in the majority the clinical picture is just as clear-cut and characteristic and as easy to interpret, and the physical examination just as satisfactory as in adults. In fact, speaking generally the diagnosis of appendicitis, if anything, is easier in the child than in the adult.

The tendency to early perforation, and the disastrous train of symptoms which so often follows, is due largely to the almost universal habit of administering purgatives in gastric and intestinal upsets, without waiting to establish a diagnosis. All are aware of the anatomical variations and anomalies met with in abdominal surgery in the young. The cecum may not have rotated or descended properly. The appendix itself is relatively much larger, longer, more funnel-shaped, contains a larger proportion of lymphoid tissue, and is much more delicate in structure. Its position is less constant, usually being located above McBurney's point. It may be found anywhere in the abdomen—in the pelvis, under the liver or well over on the left side. (I once operated upon a child in whom the under surface of the liver formed the upper wall of an appendiceal abscess. On another occasion I operated upon a left-sided, strangulated, inguinal hernia in a four-months-old infant and found the appendix and cecum in the sac.) When perforation of an inflamed appendix occurs, the delicate omentum, often veil-like in thinness, offers but a feeble barrier to the spread of inflammation. Knowing these anatomical differences, it is easy to understand why appen-

dicitis is often much more insidious in onset, the spread of inflammation more rapid, the intoxication more overpowering—in short it is not difficult to see why the disease is so serious in the very young. On the other hand, it is not reasonable to suppose that the tendency to perforation, abscess formation or spreading peritonitis, etc., is the rule in the appendicitis of this period. It is far more probable that the majority of cases, undiagnosed, it is true, go on to spontaneous recovery. I know that many cases of indigestion-colic, gastritis, gastro-enteritis, acidosis, cyclic vomiting, etc., and many acute infections accompanied by abdominal symptoms (pain, vomiting, fever, etc.) are in reality instances of unrecognized appendiceal disease. In every attack of acute abdominal pain, with vomiting and fever, it is a safe rule to assume that the appendix is involved, and then proceed to verify or rule out this suspicion. The habit of concluding that such disorders are due to dietary indiscretions and that a purgative will relieve the indigestion-colic is responsible for many deaths. Now it is a lamentable fact that there is still a high mortality—the mortality of purgation and procrastination—in a disease which should be almost free from deaths.

In Bolling's¹ series of 123 cases the mortality was only 2.5 per cent in children from six to fifteen years of age, while in the group under five years of age the mortality was 20 per cent. Over 90 per cent of this second group had an abscess or rupture of the appendix with more or less widespread peritonitis. In Beekman's² review of 145 cases in the Bellevue Hospital service, there were twenty-one cases up to six years, with perforation in every case, and with a mortality of 35 per cent. In Helmholtz's³ report of the 15 cases under five years of age at the Mayo Clinic the mortality was 47 per cent. Abt⁴ compiled from the literature eighty cases of appendicitis in children under two years of age with a mortality of 50 per cent.

These appalling figures mean but one thing, that only the worst cases, as a rule, are seen by the surgeon, and that the mortality is due to failure to recognize the disease early, or to gross mismanagement in administering purgatives when the diagnosis is in doubt. In my own series I have operated upon sixty-two little patients ranging in age from 4 months up to the sixth year, with six deaths, giving a mortality of 9.69 per cent. Eighteen cases, from 4 months up to 27/12 years of age, all recovered. There were two deaths be-

*Read at the Annual Meeting of the Medical Society of the State of New York, at New York, March 31, 1926.

supply, and the spreading of sound knowledge concerning the feeding of infants. It has as yet done little or nothing to protect the adult members of the population against the degenerative diseases which undermine the function of the vascular system, the kidneys and the pancreas. These diseases take a heavy toll of life of comparatively young people.

There is a great interest in the results of modern nutrition research, but a lack of appreciation of what is most important in their application. Thus, we have a vast fund of knowledge as to the cause of scurvy, beri-beri, ophthalmia due to lack of vitamin A, famine edema, war dropsy, pellagra, rickets, sterility due to deficient diet, defective teeth due to malnutrition during their development, and impairment of the quality of the milk through inadequacy of the food of the lactating animal. These conditions have all been produced experimentally in animals by diets faulty in specific ways. The deficiency diseases are all so spectacular as to cause wonderment that such tiny quantities of suitable vitamin preparations can induce such profound changes in the condition of a sufferer. Those of us who have had long experience in observing experimental animals are, however, deeply impressed with the evidence which we see of impending danger during the period preceding the time when clinical criteria are visible when the diet is at fault. There are foreshadowings of each type of nutritive disaster which are not so specific as the final dramatic climax in which there is failure of some specific structure or function. These are rarely considered by those who speak of the absence of disease of dietary origin in a given region. This attitude has tended to dispose of the matter and has given the impression that the diets of the people were so satisfactory as to have no bearing on the general health.

These foreshadowings in experimental animals to which I refer are changes in the texture and appearance of the hair, its lack of lustre, to loss of the usual solicitude of the animal for grooming itself, the drowsiness or

nervousness or irritability, abnormal apprehensiveness, infanticidal mania, cannibalism, etc., to which we have so frequently referred in describing experiments. These, as well as the disturbances of growth, modification of body form, such as the stockiness of animals suffering from disturbances of bone growth, faulty posture, and the attenuation of form which finally results in emaciation, are more or less specific as sequelae of defects of diet of specific kinds. They are manifest sooner than are the symptoms usually attributed to marked deficiency in diet, and doubtless appear far more frequently than these. They are the intermediary results of malnutrition, and may be due not alone to vitamin deficiency but to unfavorable composition of the inorganic moiety, or the consumption of poorly constituted proteins, etc., as well.

I believe I have never over-emphasized the importance of vitamin deficiency as compared with other defects of diet. Probably a lack of calcium, and the taking of a diet disproportionately rich in phosphorus, and lacking in the vitamin D, are the faults of greatest significance in the diet of many Americans. I have never liked to discuss vitamins in nutrition apart from a consideration of other important factors. The result is likely to be misleading, for, indispensable as are the vitamins for the maintenance of life and health, their importance is no greater than that of any other indispensable nutrients. It is especially important to disseminate the idea that any pronounced deviation from the optimal constitution of the diet will show itself in premature failure of one or another function sometime in the life history of the individual. Perfection in development and the adherence throughout life to a diet approximating the optimum as nearly as possible should be the objective. It is beyond the scope of this article to consider the ways and means for accomplishing this. I have set forth my views on the practical application of the science of nutrition in daily life elsewhere.*

have never seen a hernia follow in a clean case and it is exceptional to see one in drainage cases, where this method is properly carried out. After operation, in selected instances, measures which combat shock, tissue desiccation and toxemia, such as external heat, appropriate stimulation and sedation, and the introduction of fluids by intusion, hypodermoclysis or proctoclysis, are indicated.

CONCLUSIONS

(1) Appendicitis is not a rare disease in early life, but it is rare to have it recognized early.

(2) Contrary to popular teaching, young subjects show remarkable resistance in combatting this disease. There is practically no

mortality in properly handled cases, and the mortality is far less than one would expect in the grossly mismanaged ones.

(3) Purgation and procrastination account for the majority of the deaths.

COOPERATION FOR PREVENTING DELINQUENCY *

By RALPH P. TRUITT, M.D., NEW YORK CITY

Director Division on Prevention of Delinquency National Committee for Mental Hygiene

CRIME has a tremendous fascination for all of us—it is dramatic, always finds newspaper space, furnishes political issues and appeals at once to the Jesse James and the reformer in each of us.

Crime has a status of its own, so much so that, in some instances, committing a crime of the sentimental sort gives liberal entree to the news columns and occasionally paves the way for notoriety on the stage. However, it matters little whether the question involved is one of "moral turpitude," scandalous finance or jewel robberies—crime has an appeal to all of us.

So-called "crime waves" are, as a matter of fact, constantly with us although they do not always gain "wave" prominence in the public eye. Crime crusades fall in line with the waves and are always directed toward the wholesale disposal of the problem. Crusades invariably arouse the politician, the violent untrained reformer, and the frightened newspaper public and place in the hands of these people the whole question. If crime waves and crusades do nothing else they give the police a chance to blame the automobiles, the lack of swift cars and the smallness of their force to cope with the situation, they enable prosecutors to blame the bail bonding nuisance, the slowness of the court machinery, the police and the things blamed by the police, they afford an opportunity for judges to blame any or all of the things mentioned and in addition to lay their specific troubles to the jury service they receive, the laws under which they operate and the "coddling" parole system.

The ever present topic of crime furnishes an

open season not only for public officials, but for the public at large and there is little hesitation on the part of any of them to rush into print and appear before Kiwanis and Rotary clubs with their hurriedly gathered ideas on any phase of the crime situation. They run the gamut of causes from prohibition to rolled stockings and as amateur criminologists offer many solutions. Crime is one of the favorite topics of the day for interviews or sermons but rarely do any two people—even a judge and a minister—agree about its causes and the methods at fault in handling it. The fact that it is left to popular opinion as a burning moral issue accounts for our failure to deal with it and our preoccupation with its spectacular results to the neglect of study of its sources.

After all, the question is too complicated for laymen to handle and yet it is a problem which no one group of so-called "experts" can solve by themselves. The psychiatrists and criminologists have obtained an uncertain foothold in this field but their weakness arises from the fact that they are professionally limited to special phases of the subject and their limitations have been so obvious that the layman discredits whatever contribution they have made as sentimental and protective of the criminals. Crime does not spring from a single root and we psychiatrists are going to do very little about it until we convey to other professions their responsibility for studying the problem from their angle and joining us in a united attack on it.

There may be some doubt about the application of scientific medical principles to the study of crime and its treatment. The common belief that the function of medicine is limited to the treatment of physical disease, its cause and pre-

* Read before a joint session of the Public Health Section and the section on Neurology and Psychiatry at the Annual Meeting of the Medical Society of the State of New York March 31 1926.

tween 3 and 4 years, two deaths between 4 and 5 years, and two deaths between 5 and 6 years of age. Four boys and two girls were among the fatal cases.

The etiology is a matter of conjecture in the majority of cases. So many times, however, have I seen appendicitis develop during an attack of tonsillitis or influenza or other acute infection that I am always ready to blame the appendix, if pronounced abdominal symptoms are manifest, and to consider the possibility of an hematogenous infection. The presence of fecal concretions in an appendix means faulty drainage and is always associated, in my experience, with more or less inflammation of this organ. In several instances I have found foreign bodies as a cause of appendicitis. In this connection might be mentioned intestinal parasites, notably pin worms—as a causative factor. Tuberculosis of the appendix was found in one or two of my cases. For several years, when operating upon right sided inguinal hernia, I have made it a practice to examine the appendix through the internal abdominal ring. About seventy-five per cent of such cases will show such definite macroscopic and microscopic evidence of disease as to warrant the removal of the appendix. Again I wish to call attention to the fact that appendicitis or appendicular irritation is one of the most important factors in causing intussusception in infants. I would like to ask that the relationship between hernia and appendicitis and between appendicitis and intussusception be studied by other surgeons.

I can add nothing to what has been said over and over again as to the symptomatology, the diagnosis and differential diagnosis and as to treatment. When an adult develops acute abdominal pain with vomiting and fever, he tells the world, including his doctor, about it, and the first thing his doctor thinks about is appendicitis. This organ is always given a third degree interrogation. When a child develops a similar condition, about the last thing that is thought about is appendicitis. Often—too often, in fact—no physical examination is made until late in the disease. I believe that this failure to examine a young subject, rather than the difficulty of interpreting such an examination is responsible for the relatively large number of late cases seen by the surgeon. In patients under $2\frac{1}{2}$ or 3 years of age examination under light narcosis is often necessary in order to establish the diagnosis. Here all subjective aid is lacking, and the history as related by the parent and the physical examination must settle the question. Point or localized tenderness is the most important objective sign, and when associated with abdominal pain, which tends to focus in

the appendix zone, nausea and vomiting, and rise of temperature shortly after the onset of pain, gives sufficient evidence upon which to base a diagnosis of appendicitis. The white and differential blood count may be of help, but often it is misleading and it is not so reliable as in older patients.

In the differential diagnosis, it is important to exclude pleural and pulmonary inflammation and lesions of the right kidney or ureter. A circumscribed or central pneumonia, or a diaphragmatic pleurisy, without physical signs may be mistaken for appendicitis. The minutest attention to details is necessary in order to avoid errors. Winters years ago made the statement that "abrupt onset, high temperature, pungent heat of skin, somnolence, alteration of the pulse—respiration ratio, misplacement of respiratory pause, short, quick, audible expiration, remittent type of fever, make a clinical picture labelled pneumonia, even with every physical sign absent." If in doubt the question can be settled by X-ray examination of the chest. Now I am not going into the differentiation of appendicitis from (1) gastroenteritis, (2) intussusception and other forms of intestinal obstruction, (3) acute mesenteric adenitis, (4) peritonitis of unknown origin, (5) pyelitis or stone affecting the right kidney or ureter, (6) pyosalpinx, inflammation or growth of the right ovary, (7) inflamed, undescended right testicle, (8) duodenal ulcer, (9) infections of the right hip, etc. What I want to emphasize is this fact, that appendicitis may complicate pneumonia, influenza, tonsillitis, measles, typhoid fever, and the various affections mentioned. Never be satisfied with a single diagnosis of measles or tonsillitis, or what-not in the presence of pronounced abdominal symptoms, otherwise appendicitis is occasionally going to be overlooked.

Early recognition and prompt surgical treatment of appendicitis give almost uniformly good results. Delay in the recognition of the disease, or in instituting surgical treatment, gives not only a high death rate, but the morbidity is enormously increased among the patients who recover. Today the surgical treatment is fairly well standardized and its details will not be repeated before this body of surgeons. I would like to mention one or two points, however, which have proved helpful in my own experience. After trying out various incisions, such as the McBurney intermuscular separation, the Deaver split rectus approach and the Kammerer para-rectus operation, I believe that the latter incision (the para-rectus) is the best for all types of cases, and it is by all odds the best approach to the appendix if drainage is required. I

dowment and intelligence and investigate his behavior reactions as responses of the total organism to the environment and experience to which it has been exposed. The method is medical even though the germs we seek may reside in such non-medical fields as family relationships, school conditions and methods, housing and neighborhood problems, industrial maladjustments, social difficulties and poverty. I am stressing the fact that the method is essentially medical because this point is so little appreciated even in the public health group. The average physician fails to see that the field of personality and behavior disorders is a medical field simply because the content of that field seems to belong to such foreign provinces as those of morals, religion and the law. Psychiatry has made a great advance in identifying the field of behavior as its natural territory but its control will not be assured until the whole profession recognizes the content of this specialty and joins the psychiatrist in fighting for a truly medical scientific approach to problems on which every layman thinks himself an expert.

The average community is unable to meet the obligations imposed by such preventive work as child guidance because the community as a rule is not yet meeting the problems of health, schools, housing, unemployment, dependency of unavoidable sorts, etc., which contribute to problems of personality and behavior. In addition, there is often a feeling that preventive work is a luxury and perhaps child guidance work will have to be chiefly carried on by the various foundations until communities understand their needs and desire assistance in dealing with the problem child. The expense of developing methods for preventing delinquency should no longer be an excuse for neglect. All of us will agree, I believe, about the costliness and the failure of present methods of dealing with crime. Most of us will undoubtedly recognize the difficulties of working out a scientific approach so long as the entire problem remains in the hands of politicians and lawyers who scoff at the views of medical men and sociologists. Available statistics indicate that about 500,000 men, women and children enter various correctional and penal institutions each year in the United States and a recent estimate of the annual cost of crime reaches a total of ten billion dollars.

However, the arguments for prevention cannot be based as yet on financial economy. Prevention is expensive and its results are not always convincing to those who feel that what is prevented might not have developed in any case. We who have been working to formulate methods of preventing delinquency have discovered no magic prescription. We have discovered through diagnosis and treatment that prevention involves innumerable fields other than our own and that constructive work for eliminating the causes of delinquency demands that those responsible for other phases of human welfare see their job as related to ours. For instance, two great preventive agencies are the parents and the schools. They are directly concerned with the physical, mental and emotional development of children and the methods they use determine the fate of the child long before the question of delinquency or mental health arises. It is with them that we have to work out methods of preventing delinquency. This entails giving them insight into the factors operating to produce mental and physical health, interesting them in co-operation for the study of the material with which they deal, working with them to shape methods for handling the everyday problems even the normal child presents and then exploring other fields of human activity to locate in them their peculiar foci of irritation. Prevention of behavior problems is no monopoly of the psychiatric group whose isolated efforts involve a struggle against all sorts of undercurrents in the fields of industry, law, education, public health, housing, politics, etc. Psychiatry will operate in a vacuum until it can join forces with preventive work in other fields and evolve with them common methods of preventing difficulties which contribute to undermine public health—mental and physical. Our methods for preventing delinquency will be only partially effective as long as allied groups fail to understand our purposes and to see how our work may re-enforce theirs. We have the essential scientific machinery for attacking the problem and many unexploited resources in the preventive work of other fields. We need co-ordination of effort and above all general medical support to remove the question from the field of popular speculation and apply to it scientific methods of study and treatment.

PERIODIC HEALTH EXAMINATIONS*

By CHARLES S. PREST, M.D.

UPON the invitation of your Chairman I am glad to outline to you the conduct of the campaign for the promotion of the habit of periodic health examinations in

* Read at the Annual Meeting of the Medical Society of the State of New York at New York, March 31, 1926.

Kings County. This work is not a new story in Kings. In 1915 the promotion of periodic health examinations was included as a part of the program of the Brooklyn Tuberculosis Committee, this committee then, as now, being the official local representative of the National

vention, still prevails in some quarters even though it is some years since medical boundaries were extended to include such disorders as "lunacy." An enlightened public now realizes that the very term "lunacy" is a relic of the past, mental diseases are losing their ugly social stigma and psychiatry is more and more understood as that branch of medicine dealing with personality and behavior disorders. Certainly the entrance of medicine into this field has resulted in constructive changes in the treatment of mental disease, a healthier attitude in the general public and the establishment of the field as a professional one for scientific study.

While the behavior disorders of the mentally diseased and the criminal do not necessarily follow the same pattern, they spring from related roots in the maladjustment between the individual and his environment. If we are correct in assuming that behavior is the expression of the whole organism, through its various system activities, to environment, experience and training surely medicine is interested in attempting the study of crime. It must be accepted that crime represents behavior "gone wrong" although its pathology may not be studied like bacteria under the microscope. Preventive medicine has frequently ventured afield from bedside medicine in studying those conditions which influence the health and efficiency of individuals and the general public health movement has been organized to improve man's environment to eliminate disease factors. Public health efforts have penetrated into such related fields as sanitation, industry, education, social welfare, housing, etc., professional alliances have been formed and accurate ideas of the purpose of public health work have been transmitted to other strategic groups. Medicine's method of approach to general public health must be similarly applied to the problems of crime. Scientific medicine cast aside the popular prejudices that had resulted in jailing lunatics, refused to be content with dismissing lunacy as a moral offense and instead accepted it as a diseased condition to be scientifically studied and treated. Just so should medicine refuse to allow crime to rest in the hands of excited laymen more intent on punishment than understanding. Medical pressure should be brought to bear for recognition of the subject as one properly within the province of medicine where its causes and treatment can be studied objectively, and preventive methods may be evolved.

Prevention worthy of the name offers few of the popular thrills associated with crime crusades. Only when the scientific discovery of an elusive bug or the cure for a distressing malady is found, is public interest aroused. Society for the most part is easily satisfied and points with pride to its institutions for contagious diseases, for the insane and for criminals. Medicine has

had to take the initiative in progressing beyond its early achievements in caring for end-results to work preventing the development of those results. It has had to rescue various problems from purely lay control, study them without prejudice and then educate the public to a more constructive point of view.

In dealing with delinquency, scientific attention has been increasingly focussed on childhood. This is in keeping with preventive medicine in other fields. The problem child is the forerunner of the problem adult as the clinical histories of the majority of the adult personality and behavior problems demonstrate. However, there is considerable impatience with psychiatric work for children because of the apparent triviality of children's problems. The present situation is not unlike that period in medicine when children were supposed to have all the infections and contagions traveling about so that they would "get over them" while young. The chief difference is that children are expected to "outgrow" their psychic infections and contagions without even the equivalent of treatment accorded children's diseases. The accepted basis for work with problem children is the fourfold attack from the fields of medicine, psychiatry, education and social work and the assumption that there are definite causes for personality and behavior problems outside of original sin. Fundamentally, our method of attack is a scientific medical one, that is, we investigate conduct disorders objectively as symptoms indicating the operation of underlying factors. We cast aside our moral prejudices and social judgments and think in terms of cause and effect. Even in the simplest behavior problems we find that the difficulty has multiple roots in every phase of the child's life and that the child's behavior is strictly determined even though the germ is not a specific organism. Take such a symptom as stealing. A youngster may steal because he has an unsatisfied craving for sweets, or because he has the desire for playthings or movies which other children have, or because he has never grasped the distinction between his and other people's property. His gang may steal and he joins in to prove his right to membership. In short, the stealing may be traced back to a physical condition, to a lack of normal opportunities, to bad neighborhood influences, to a misguided attempt to stand well with others, to the poor example set by the parents or any of a hundred other conditions. It is as unjustifiable to treat stealing as an entity in itself as it would be to treat fever as a disease instead of a symptom. And though society will continue to punish such offences, such measures are as irrelevant to treatment of the delinquency as they would be to a toxic delirium. To understand a given behavior problem we have to explore the child's physical condition, estimate his native en-

found to be financially unable to pay a private physician for this service

After the literature and health examination blanks had been distributed to the members of the medical profession of the borough and the various meetings of physicians held, upon the recommendation of the Medical Committee the lay group inaugurated their campaign for the promotion of health examinations among the lay public. This campaign has included a large amount of literature for distribution, the showing of several series of car cards and station platform posters in every subway, surface and elevated car of the borough and on every station platform, and a large amount of newspaper publicity urging the adoption of the habit of having a periodic health examination under the slogan coined by the committee "Have a Health Examination by Your Physician Before Your Birthday." In every instance the point was stressed that these examinations should be made by the physician of the choice of the individual, no examinations being conducted by the committee except in the dispensary of apparently healthy poor persons referred to it.

Health examination blanks are provided physicians upon request without charge, each physician being asked to detach and return to the committee a notation as to the findings and recommendations, without identifying marks as to the person examined. These are for tabulation and statistical study, reports of which have been made at various times.

In Queens Borough similar work has been carried on by the Queensboro Tuberculosis Association, they distributing there the American Medical Association health examination blanks and making available the manual in regard to periodic health examinations of the American Medical Association to every physician.

In addition to the above, upon the recommendation of the speaker, the Brooklyn Tuberculosis Committee and the Queensboro Tuberculosis Association have each made an appropriation of \$1,000 for post-graduate medical education in preventive medicine during the current year. This is to be carried on in cooperation with the Committee on Post-Graduate Medical Education of the Kings and Queens County Medical Societies. This is mentioned here as it is expected that post-graduate medical education regarding periodic health examinations will be included as a part of this work.

While the acceptance of the plan of periodic health examinations of apparently health persons by physicians generally has not met with

unanimous response by any means it has been enthusiastically received by many. The pediatricists particularly are found to be conducting such examinations in increasing numbers, parents being found not only willing but anxious to have their children examined regularly by their physician although they do not generally apply for such examinations for themselves. The outlook is most hopeful, however, and has already resulted in materially increased practice for a number of physicians, they by this method being consulted for professional advice much more frequently than in the past.

The Public Health Committee of the Medical Society of the County of Kings has recently issued a special report on periodic health examinations of apparently healthy persons which is available for a small charge upon application to the Society. This includes copies of the form of blank prepared by the American Medical Association as well as that by the Brooklyn Health Examination Committee. Copies of many of the pamphlets in regard to health examinations issued by the Medical Society and the Health Examination Committee are also included as well as considerable other information of value in connection with this work.

Those present are no doubt familiar with the fact that the Metropolitan Life Insurance Company has prepared an interesting motion picture for the promotion of periodic health examinations among lay persons. The title is "Working for Dear Life" and I am advised it is available for exhibition without charge through application to any local Metropolitan agent. The Brooklyn Committee secured six copies of this film and through the cooperation of the Theatre Owners Chamber of Commerce, over 200 showings were given in Brooklyn, as a part of the regular program of some forty theatres, thus carrying the message of health examinations to a very large number of people. In addition to this the New York Tuberculosis and Health Association has about completed a technical motion picture regarding periodic health examinations for exhibition before physicians. This is to have a primary showing very shortly and it is expected it will be exhibited at the meeting of the American Medical Association in Dallas this year.

The speaker is glad to relate this history of the work in Kings and Queens Counties based upon what has been proven to be a sound and ethical plan and if we can help in promoting this work elsewhere we will be glad to render any assistance that we may.

Tuberculosis Association for the boroughs of Kings and Queens. When the Queensboro Tuberculosis Association was organized by the Brooklyn Committee in 1920 the promotion of periodic health examinations was included as a part of their program and they are still continuing this work in the Borough of Queens.

Upon the adoption of the policy of promoting periodic health examinations by the fourteen National Associations represented in the National Health Council in 1923, after the endorsement of such work by the American Medical Association in 1922, the Brooklyn Tuberculosis Committee was invited by the National Health Council to assume responsibility for the conduct of this work in Brooklyn, and through its local, the Queensboro Tuberculosis Association, in Queens Borough.

In response to this Mr. Frederic B. Pratt, the President of the Brooklyn Tuberculosis Committee, called a dinner conference of representatives of the Kings County Medical Society, the Department of Health, the Public Health Committee of the Chamber of Commerce, and a number of representative citizens to consider the invitation to undertake this work. The whole matter was discussed at considerable length and it was finally decided to organize a special committee of representatives of the various health agencies of the borough and a number of representative citizens to be known as the Brooklyn Health Examination Committee, they to be asked to be the sponsor of this work. Upon recommendation of the speaker, it was decided to carry on this campaign separate and distinct from the work of the Brooklyn Tuberculosis Committee, the health cross, the emblem of the work of the latter committee, not to be carried on any of the literature or other material of the Health Examination Committee. The purpose of my suggesting this was to divert the campaign in the minds of the general public from one against tuberculosis alone, it being our experience that the public considered periodic health examinations in this limited sphere only.

The Brooklyn Tuberculosis Committee volunteered to underwrite the campaign for the first year by an appropriation of \$5,000. The same amount was provided by the Brooklyn Tuberculosis Committee for this work last year and a like amount has been granted for the current year. The expenditures for this work have somewhat exceeded these amounts each of the past two years, the deficit being met by the Brooklyn Tuberculosis Committee. In addition to the financial grants made by the Brooklyn Tuberculosis Committee, part of the time of the speaker was made available to the Health Examination Committee as well as such stenographic and clerical assistance as needed.

After the formation of the Health Examination Committee with the appointment of a prominent resident of the borough as a lay chairman, it was immediately decided to place the responsibility for the promotion of the work among physicians in the hands of a medical sub-committee of which Dr. Glentworth R. Butler accepted the chairmanship. The promotion of the work among the laity by the general committee was withheld until the medical committee might organize the work among the physicians of the borough. With the close cooperation of the Public Health Committee of the Medical Society of the County of Kings the Medical Committee held frequent meetings and whipped into shape a form of blank for adults and another for children that provides a carbon copy of the examination made by the physician to be given to the person examined. The committee issued a special announcement together with special literature in regard to health examinations to the medical profession of the borough and placed a supply of blanks in the hands of each of the twenty-seven hundred odd physicians. Upon presentation of the plans of the Brooklyn Health Examination Committee by the chairman of the Public Health Committee of the Kings County Medical Society the Society unanimously endorsed the work at a regular meeting. The Medical Society of the County of Kings devoted a special meeting of the Society to the promotion of the work. It also devoted one of its regular Friday afternoon lectures to the demonstration of the conduct of a periodic health examination. Subsequently the Public Health Committee of the Medical Society arranged for the examination of ninety-seven physicians by their confreres, and at various times have issued a number of leaflets to the medical profession regarding periodic health examinations.

Intercurrently with this the motion picture "Working for Dear Life" was shown at a staff meeting of each of the hospitals of the borough, representatives of the Medical Committee of the Health Examination Committee addressing the staff on the subject of periodic health examinations in each instance.

Upon the recommendation of a special committee of hospital representatives the Health Examination Committee established the first licensed dispensary for the conduct of periodic health examinations of apparently healthy poor persons in the Brooklyn Bureau of Charities building and have continued this dispensary. This is only for periodic health examinations of apparently healthy poor adults and children referred to the committee by physicians and social and welfare agencies and only such persons are examined as after careful inquiry are

ARTIFICIAL RESPIRATION

About 2,000 deaths occurred in New York State during 1925 from causes in which artificial respiration is the proper treatment, of which 857 were due to drowning and 852 to gas suffocation. Probably an equally large number of cases recovered after artificial respiration had been done. It is a conservative estimate that at least 5,000 persons of New York State require artificial respiration each year. This is an average of about one case per doctor once every three years. Yet any doctor, or any other person, may at any time, be confronted with a case requiring artificial respiration. The method may be learned so easily that it is taught to boy scouts, and to employees in gas and electric companies, and when an emergency arises, these amateurs are able to apply the method with skill. No doctor should permit a layman to excel him in the knowledge of any life saving method.

The suggestion for this editorial came from the medical staff of a small hospital. During its monthly meeting a call came for the pulmotor. There was a delay in finding it, and then it was discovered to be out of order. One member of the staff remarked that he had heard that some other method was as good as the use of a mechanical device, but no one could speak with authority and knowledge. A committee was then appointed to study the subject, and present its findings at the next meeting. The report of that committee clarified the whole subject in the minds of the members of the staff.

A decade ago the insurance companies writing accident policies for gas and electric light companies advocated that mechanical devices for doing artificial respiration be purchased by the insured and by hospitals and fire companies. These appliances were advertised so widely that now, when a case of drowning occurs, everybody thinks of a pulmotor as the very best means of restoring life. There are two serious objections to a mechanical device.

1 The delay in bringing it to the patient.

2 It is no better than the "Prone Pressure," or "Schafer" method, which any one can do anywhere that the patient may happen to be.

The whole subject of artificial respiration has been thoroughly investigated by the U. S. Government Bureau of Mines, and by Dr. Yandell Henderson in the Physiological Research Department of Yale University. Dr. Henderson presented a summary of his findings in the *Journal of the American Medical Association* for September 6, 1924. He specifically says that the Prone Pressure method is superior to any other method, or to a mechanical appliance, in causing air to enter and leave the lungs, and he advises

its immediate use in all cases requiring artificial respiration. The only additional measure which he advocates is the use of oxygen containing five per cent of carbon dioxide as a stimulant of the respiratory center in cases of carbon monoxide poisoning. Every doctor should know of Dr. Henderson's work, for it is the basis on which the modern standard of doing artificial respiration are founded.

A doctor called to a case of drowning, gas asphyxiation, or electric shock must choose one of three well-known methods of doing artificial respiration, namely, 1, the "Sylvester" method in which the patient lies face upward, 2, the "Mechanical Device" method (the pulmotor, for example), and 3, the "Prone Pressure" or "Schafer" method. The doctor who uses the Prone Pressure method has the satisfaction of knowing that it is the standard method that is approved and advised by the highest scientific authorities. This is a legal point of great importance. The law of negligence may apply to a doctor who fails to use the best method of artificial respiration, and, vice versa, the law will uphold him if he uses it to the exclusion of all other methods.

Doctors should know another legal point. The return of breathing may not take place until artificial respiration has been done for two or three hours. A doctor acts to his own peril when he pronounces a patient dead and orders the cessation of artificial respiration. The insurance companies quote cases in which laborers have persisted in doing artificial respiration after doctors have pronounced the patients dead, and have restored the patients to life,—to the discredit of the doctors. It has even happened that a doctor has forbidden a workman from continuing the artificial respiration for the reason that the patient was dead, and the workman has replied, "If you say the patient is dead, you have nothing to do with the case. I am going to do artificial respiration for three hours, if necessary, as I have been taught." The workman is right in taking this attitude.

A physician does not really know how to do artificial respiration unless he not only practices it on a subject, but also allows some one to do it to him. When he lies upon the floor and lets a husky colleague squeeze the breath out of him, he realizes the exact amount of pressure to apply, and how and where to apply it.

The importance of this subject would justify its presentation as a part of the educational work of the Medical Society of the State of New York.

FALL ACTIVITIES

The full resumption of medical activities in the autumn finds the Medical Society of the State of New York well prepared for its fall and winter work. This number of the JOURNAL records the organization of the Grievance Committee, the completion of plans for the first statewide registration of physicians, the assignment of two Deputy Attorney-Generals for the enforcement of the Medical Practice Act, the first official conference of secretaries of County Medical Societies, and the plans for the annual meetings of seven out of the eight District Branches.

The fall opens auspiciously for organized medicine in New York State. The stimulus of the State and District Branch Societies should be felt in the county medical societies, which also resume their work. More of their work should be recorded in this JOURNAL. The editors cannot go to the county societies to seek information—the news must come from the local secretaries and reporters. The pages of the JOURNAL are open to the local societies for publicity and for mutual helpfulness.

MEDICAL PROGRESS

Tannic Acid in the Treatment of Burns — About a year ago E C Davidson, writing in *Surgery, Gynecology and Obstetrics*, suggested the application of tannic acid in the treatment of burns. His method is first, after a preliminary injection of morphine, to cover the burned area by dry sterile gauze pads held in place by sterile gauze bandages, and then to soak this dressing with a freshly prepared 25 per cent aqueous solution of tannin. The area is inspected at the end of twelve hours and every six hours thereafter until it is seen to be of a uniform light brown color, then the dressings are again soaked with the solution and, when no longer adherent, are removed and the surface is left exposed to the air, protected by a cradle draped with sterile linen, and kept warm if necessary by one or more electric bulbs.

In the *Annals of Surgery* for July, 1926 there are two articles reporting the experience of the writers with this method. The first paper, which was read before the American Surgical Association in May of the present year, is by Frederic W Bancroft and Charles S Rogers. The authors state that they have had experience with both the debridement and the tannic acid methods of treating burns. In general they give the preference to tannic acid, though they admit that in deep burns of small surface area, immediate debridement associated with skin grafting may be of value. The disadvantages of debridement are. It is a radical procedure with considerable operative risk to a devitalized patient. Islands of epithelium in the hair follicles and sweat and sebaceous glands may be sacrificed that might have been saved. The after-treatment is extremely painful and infection is very apt to occur. Finally skin grafting must usually be performed to cover the defect, but when infection is present the grafting may be of necessity so long delayed that a second debridement must be performed to provide a satisfactory field for the grafts. When tannic acid is used the burned area is covered by a firm mahogany colored membrane of a leathery consistency. The pain in this treatment is less than in any other procedure of which the authors have knowledge. The membrane should be left to separate of itself, for epithelization occurs beneath it in superficial burns while attempts at early separation cause bleeding and with bleeding comes infection.

The second paper is by Claude C Beck and John H Powers. The authors suggest a modification of Davidson's technique, for they say a more intimate contact between the burn and

tannic acid can be produced by spraying the burn with the tannic acid solution every half hour until the surface becomes brown or black. Blebs are opened as soon as they form and the epidermis is removed wherever it separates. The burn is exposed continuously to dry heat, for exposure to air seems to facilitate the process of tanning and exposure to heat hastens drying of the coagulum. The ordinary electric heater may be used for this purpose. An extensive burn can be coagulated completely by this method in sixteen hours, a smooth, indurated, and entirely insensitive surface being produced. Toxemia usually disappears in three to five days, and then arises the question as to the proper time to remove the coagulum. If the epidermis alone is involved, the crust separates at its margin as the new epidermis grows beneath it, and it should not be disturbed until it separates, which will be in about two weeks. When the entire thickness of the skin is destroyed the epithelization takes place only at the periphery. This is such a slow process that it may be advisable to remove a part or all of the crust, according to the extent of the burned area, and place grafts on the base. The crust may be removed by softening it with vaseline and cutting it free where it is attached to the subcutaneous tissues. A tannic-acid solution of approximately 25 per cent strength may be made by dissolving four teaspoonfuls of the dry powder in a glass of water.

Sodium Chloride in Cutaneous Burns —

Edward C Davidson has made a study in a number of cases of burns of various degrees to determine the disturbance of chloride metabolism, and has found in 31 cases a lowering of the whole-blood and plasma chlorides. The diminution was more than could be accounted for by alteration of the renal threshold, diet, fever, exudation, blood concentration, or vomiting. The evidence suggested that there was retention of sodium chloride in the tissues, in general quite similar to that observed in pneumonia. This disturbance of chloride metabolism seemed to be proportionate to the amount of tissue devitalized. The analogy between intestinal obstruction with accompanying toxemia and the toxemia of burns is a close one. These findings, the writer says, suggest the advisability of the administration of sodium chloride, in cases of extensive burns, in order to correct the deficiency — *Archives of Surgery*, August, 1926.

DR WILLIAM FRANCIS CAMPBELL

Dr William Francis Campbell, President of the Medical Society of the State of New York in 1913-14, died on September 7th, aged 60, after a brief illness following an operation on his gall bladder. He was a native of Brooklyn and spent his professional life there. He had been professor of anatomy and later of surgery in the

Long Island College Hospital Medical School, and was active in medical societies and in the practice of civic medicine. He was a skilled surgeon, a clear thinker, a satisfying teacher, and a genial friend. He enriched the practice of medicine and the medical profession with his skill and attractive personality.

THE CONFERENCE OF SECRETARIES

The official conference of secretaries of the County Medical Societies that was held on September 2nd was inspiring and encouraging. (See page 798) Those secretaries who are naturally doleful and pessimistic might have found confirmation of their preconceived ideas as some secretaries told of their discouragements and difficulties, but the optimists turned the same reports to their encouragement, as they said, "I thought our society was not up to standard, but it seems to be pretty good after all. We can show some of the others a thing or two."

But there was also an abundance of constructive reports given. In fact, one could run a successful county medical society by adopting the novel plans which had been put into successful operation in the several societies. Time was too short to report all the good things which the societies had done.

Meetings of the county secretaries have been

held during the annual meetings of the State Society for many years, and the secretaries have had an organization of which Dr Harrison Betts of Westchester County was the last president. The last meeting of the organization was held during the annual meeting of the State Society as described on page 342 of the April 15th issue of this JOURNAL. That meeting voted to request the Council of the State Society to authorize a meeting of the secretaries in the early fall. The present conference was the result of favorable action taken by the Council and it is understood that the old organization automatically ceases.

The success of the first official conference amply justified the wisdom of the Council's action in assembling the secretaries in conference at the expense of the State Society. It is to be hoped that the conferences will be repeated, and that in addition conferences of the secretaries will be held during the District Branch meetings.

LOOKING BACKWARD

THIS JOURNAL TWENTY YEARS AGO

The New York State Journal of Medicine for September, 1906, has an editorial on the Pure Food Bill, which had recently passed Congress. Looking backward over the good results of twenty years of enforcement of that act, one wonders why its passage was ever seriously opposed. The editorial follows:

"*The Pure Food Bill* The passage of the Pure Food Bill is one of the hopeful signs that Congress will help the people. Against the powerful opposition of the manufacturers of questionable foods and dangerous medicines, the newspapers which they control, the wealthy Proprietary Association, and United States Senator Hemenway, the bill passed the House by a vote of 242 to 17, and the Senate by 64 to 4. This result is really a victory for the press, both lay and medical, which for the past two years has been agitating this subject. Much credit is due to the periodicals which have been engaged in the exposure of the nostrums and patent medicine frauds. The bill prohibits the interstate shipment of adulterated or misbranded articles, and provides for the examination of samples of

foods and drugs by the Bureau of Chemistry in the Department of Agriculture. The standards for drugs are those recognized in the United States Pharmacopoeia and the National Formulary. The bill becomes operative January 1, 1907, but unfortunately it has no appropriation for carrying it into effect. It requires that medicines containing narcotics and poisonous drugs shall be labelled with the name and amount of such substances.

"This bill, if provided with means for its enforcement, will be of much service to the public. It will also result in the destruction of many of the so-called household remedies which would not be used were their contents known.

"An interesting feature is that the Department of Agriculture is called upon to pass judgment upon drugs and medicines intended only for human use. While that department is the best that Washington has for this work, and as it already has so many distinctly medical functions to perform, it might occur to some that we have here another argument for a Federal Department of Sanitation or a National Board of Health."

in type, presumably early cases in which the most burdensome symptoms were lightning pains and gastric crises. The latter, in addition to the suffering caused, may be so frequent as to interfere with alimentation, and accordingly Hesse set out to learn whether the malaria treatment could modify these painful symptoms. There was no immediate question of curing the patients. In every one of these 13 cases there was notable improvement in the symptoms, while it was apparent throughout that no patient had been damaged by the treatment, this also having been the experience of Bering and Nonne. The author would therefore recommend the treatment in cases of this type and believes that it should be of curative value, for the mischief is due to the spirochete which the fever produced by the treatment will destroy, while there is no other fever-producing remedy which can compete with malarial virus.

Postoperative Colonbacilluria—As Charles C. Pinkerton says in the *Archives of Surgery* for July 1926, the appearance of the colon bacillus in the urinary tract following childbirth, disease, or injury, either accidental or operative, offers a problem of great interest to the pathologist and clinician. Many cases exist of pyelitis or pyelonephritis following gynecological or general surgical operations in which the symptoms disappear after a short time but the excretion of large numbers of colon bacilli in the urine continues for an indefinite period. This may be due to the fact that the symptoms are the expression of a primary invasion by a streptococcus or staphylococcus and that they subside when the pathogenic organism is crowded out by the comparatively harmless colibacillus, or there may be a natural tolerance of the presence of the colon bacillus in the intestine which is only temporarily disturbed when the microorganism invades the new field of the urinary tract. But this reacquired immunity may be again disturbed by trauma or by physical depression from overwork or worry weakening the resisting powers of the organism.

As a result of the author's study of an unselected series of 130 general surgical cases, made to determine the incidence and significance of post-operative colonbacilluria the following conclusions are formulated: (1) The colon bacillus appears in the urine of a certain percentage of male and female patients who present themselves for surgical operation. The same organism appears in an appreciably larger percentage after operation, often without subjective or objective symptoms of a urinary tract infection. (2) Among female surgical patients of this series colonbacilluria was present from three to five times more often than among male surgical patients. (3) Colon bacilli occurring in the urine in abundance after operation is a presumptive sign of urinary tract infection, but in the absence of other con-

firmatory evidence does not always account for postoperative complications. (4) Gynecological cases, as a class, have colon bacilli present in the urine after operation probably more often than any other class of surgical subjects.

Light and Its Therapeutics—In discussing the manner in which artificial light produces its good effect, F. Howard Humphris (*Practitioner*, May, 1926, cxxvi, 5) says we know the rays are absorbed by the blood, and that the vital processes are profoundly and beneficially affected by them. Among the changes produced in the chemistry of the blood is an increase in its calcium, phosphorus, and iron content. Other effects are due to an increased activity of the vitamins, and others, again, to the stimulation of the endocrine glands. The general or systemic changes, as summarized recently by W. E. Dixon, are mild stimulation of the medullary centers, slight increase of pulse rate, stimulation of respiration, increased activity of the tissues, as shown by an augmented power of phagocytosis, and an enhancement of the hemobactericidal power of the blood. One of the best known results is the production of erythema which is brought about thus: the light excites the nerve endings in the skin, owing to the power of the light to create fluorescence in the presence of hematoporphyrin and possibly other substances in the skin. This fluorescence produces an irritation of the sensory nerves, which dilates the blood vessels in the skin and subcutaneous tissues. Another effect is pigmentation, which may be in some way related to endocrine balance. In addition to its antirachitic properties actinic light possesses rejuvenating powers. It has an undoubted influence for good upon muscular agility and mental activity. Aside from its recognized value in lupus, it has proved successful in a long list of dermatological conditions. Those in which it has given the greatest success in the writer's experience include furunculosis, eczema, alopecia, especially alopecia areata, onychia, chilblains, Raynaud's disease, psoriasis and pruritus. Other therapeutic uses for this agent are found in anemia, digestive disorders, and gastritis with acidity, and even gastric and duodenal ulcers have been benefited by it. It is useful in disordered menstruation, especially in those undergoing x-ray treatment for the production of an artificial menopause. Troublesome cases of neurasthenia and certain cases of nervous disease, especially insanity, in which it has been shown that the phosphate ratio is lowered, have shown marked improvement under ultraviolet radiation. It also has the power to relieve pain in sciatica, lumbago, and other forms of fibrositis and neuritis. It is an excellent remedy for a general "run down" condition and the ideal treatment of health, since prevention is better than cure.

A Substitute for the Argyrol Pack in Accessory Sinus Drainage—J B H Waring writing in *The Laryngoscope* for July, 1926, comments on the efficacy of the argyrol pack in promoting depletion of the tissues in congestion and inflammation of the nasal chambers and accessory sinuses, but says that this treatment is "messy" and on this account often objected to by fastidious patients. To remove this disadvantage he suggests the substitution for the silver salt, of a saturated solution of Epsom salts in glycerin which is not only colorless but inexpensive. It also keeps better than the argyrol and is ready for use over a considerable period of time if kept in a well stoppered bottle. The author admits that the substitute lacks the antiseptic properties of the silver preparation, but he thinks it is questionable whether much antiseptic power is exerted on the nasopharynx and sinuses as a whole during the stay of the pack in the nasal cavity. Incidentally Waring remarks that this magnesium sulphate solution will be found of value as an application for sprains, bruises, and other superficial congestions and inflammations.

Peroral Immunization—Hans Leiter traces the beginnings of this subject to 1905, when Wassermann figured as a pioneer in the attempt to increase the permeability of the gastric mucosa and thereby facilitate absorption. Bez-redka believed that he had found such a substance in bile and Wassermann corroborated him with the discovery that the bile salts were the responsible portion of the secretion. Later at the suggestion of Wassermann a research established that there is an entire group of substances which possess this property for which the term "hydro-tropic" was coined, the salts of bile being among the number although the most available member of the group seems to have been sodium benzoate. The present author has conducted experiments on rabbits who were made to swallow cultures of typhoid bacilli, Shiga dysentery bacilli, and other pathogens after previous ingestion of antigen substances, which in turn followed preliminary treatment with solution of sodium benzoate taken on a fasting stomach. The results were encouraging. In regard to man, the author admits his ignorance and the clinician will have to solve the problem himself. We have no idea as to what antigen doses should be given nor do we know what diseases are the most promising for the purpose. We do know that sodium benzoate is quite harmless and has been used freely in typhoid fever. The author suggests that the best diseases to test the buccal type of immunization should be typhoid fever, puerperal fever, and diphtheria among the specific infectious diseases, while furunculosis promises well as a type of a chronic recurrent malady.—*Deutsche medizinische Wochenschrift*, June 4, 1926.

Vaccinal Treatment of Syphilis—Professor Hilgerman has treated with fair success a number of cases of syphilis with inoculation of living spirochetes, the aim of this superinfection being to arouse the production of immune bodies in greater amount than occurs spontaneously. Especially does vaccination seem indicated in cases treated with arsphenamine because this substance may destroy *en masse* an enormous number of spirochetes with resulting exhaustion of immune substance in the tissues. The system then being without any defense, a negative phase develops. There is also a possibility of damaging the tissue cells permanently or of encapsulation of spirochetes with the possibility of neurotropic lesions. If in place of the large, sterilizing dose of arsphenamine we employ small and often repeated doses we run a risk of setting up acquired tolerance to the drug. The author first tried vaccination with ordinary cultures but obtained no satisfactory results, so then, with Krantz, he treated 47 patients by vaccination with secretion from open lesions which contained virulent spirochetes. The immune behavior to luetin was first ascertained and was found to be strongly positive in the second stage while in later syphilis and in latent and hereditary cases it was either weakly positive or negative. The "spirochetic pus" as the author terms his living material was inoculated intradermically and the reaction was much like that of luetin save that some patients negative with the latter gave positive results. Repeated injections gave the same reaction, thereby showing good defense. By continuing the injections the therapeutic efficacy was manifest, for the patients improved strikingly. But it was impossible to use the intradermic method for treatment, owing to the large lesions produced *in situ* which healed with scar formation. The injections were therefore given by the hypodermic or intramuscular route.—*Muenchener medizinische Wochenschrift*, June 11, 1926.

Treatment of Tabes With Inoculation Malaria—In recent years there has grown up a very extensive literature on the malarial treatment of paresis, but this has no counterpart in the management of tabes. One reason for this is apparently that tabetic patients are not interned together in large numbers like the victims of progressive paralysis. Several small series of cases have been reported, one of 23 by Bering and another of 36 by Nonne, which are analyzed by E. Hesse in the *Medizinische Klinik* of June 11, 1926. If we were guided by the results obtained in these 59 cases the malarial treatment would have to be pronounced a failure. But details are lacking as to the type or stage of cases treated, and the remedy cannot be condemned outright without further trial. The author thus far has had 22 cases of tabes under the malaria treatment but 4 of these are too recent for analysis. Of the balance 13 were remarkably similar

Counsel, Medical Society of the State of New York

FIBRO SARCOMA—ROENTGEN RAY REACTION

This was an action instituted against a physician specializing in roentgen ray treatment. The complaint charged that in July, 1922, the plaintiff was suffering from phlebitis of her right leg, the inner surface of the right thigh, particularly the right groin, that at that time she consulted the defendant as such specialist and after examination she was advised by him to receive X-ray therapy to cure or alleviate her condition, that the defendant undertook to treat her with X-ray therapy and that by reason of his negligence and carelessness she was severely burned during the treatments so that the outer surface of her thigh became intensely swollen, discolored and extremely painful, and her left leg was severely burned. It was further charged that the plaintiff by reason of defendant's negligence was caused to suffer great pain, that the injury to her right leg resulted in an ulcer and her left leg was burned and swollen and that she was obliged to submit to operative interference in an endeavor to cure the injuries, that she had been and will be confined to a hospital for a long period of time, that she was permanently incapacitated and bedridden since the claimed X-ray burn and that her right leg may have to be amputated as a result of the injuries. She asked damages in the sum of \$75,000.

The defendant first saw the plaintiff when she was referred to him by a pathologist who had examined her at the request of her family physician. She had been under treatment for some period of time by the family physician who had diagnosed her condition as phlebitis. The plaintiff was a married Jewish woman about 32 years of age who had three children, her last pregnancy occurring about ten years prior to July, 1922, and six years before the appearance of the condition complained of. On examination her pelvis was found to be normal. There was no history of pelvic infection or any infection of the leg or foot to account for phlebitis. She stated that her present trouble was first noticed by the appearance of a small lump on the outer side of the right thigh, the condition being accompanied by pain. At that time she consulted the family physician who after examination, advised the extraction of her teeth. Eight teeth were extracted, but she was not relieved from the pain. She was confined to bed and the swelling of the lump on the outer side of the thigh increased. For several months this lump was treated with various applications of oils and ointments. A

similar mass appeared on the front of the thigh and then the masses seemed to come together. A nodule also appeared upon the left thigh. Thereafter she was referred to a pathologist who in his examination found there were hard lymph nodules in the right groin. After his examination she was referred to the defendant for X-ray examination.

On July 25, 1922, from different angles three radiographs were taken and a visual and manual examination made. As a result of these examinations the defendant found a large indurated mass in the right thigh beginning at a point in the middle of Poupart's ligament and extending downward for about eight inches, the margins of the mass were not clearly defined and the mass extended into the surrounding tissues, its outline was somewhat irregular, being about three inches by a half inch, the skin was brawny and red, the mass moved with the deeper tissues and could not be distinctly separated from the skin, the mass was adherent to the skin and involved the skin. As a result of this examination the defendant made a diagnosis of fibro sarcoma of the right thigh, nodule of the left thigh anteriorly, with no bone expansion and no osteomyelitis. He recommended X-ray therapy for the treatment of the condition.

On July 26th and August 2nd X-ray therapy was administered to the plaintiff. The portals of treatment and the factors of dosage were as follows:

Date	Location	Portal	Size	K B	Dose Filter	Dist.	Time	Diag.
July 26—	Anterior right				1/2 Cu			
	Thigh		M	200	1 Al	55	100	4 mills
Aug 2—	Lateral right				1 Cu			
	Thigh		9x12	200	1 Al	50	60	4 mills
	Anterior				1 Cu			
	Left Thigh		8x8	200	1 Al	55	25	4 mills

In the administration of the X-ray therapy the defendant gave sufficient dosage to the tumor mass in order that it be destroyed and so that every part of the tumor mass would be covered by the X-ray therapy. She was seen by the defendant on July 28th, two days after the first treatment, at which time he prescribed an ointment to be applied three times daily over the radiated area. The prescription of this ointment is a general custom with the defendant and is given to all patients who have received X-ray therapy. Accompanying the prescription were instructions to the patient not to apply any irritant to the radiated area nor adhesive plasters or

Pathogenesis of the Fox-Fordyce Disease—Walther Pick (*Archives of Dermatology and Syphilis*, June, 1926, xiii, 6) says that investigators have usually classified Fox-Fordyce disease as a nervous condition belonging to the neurodermatitis group. The cases which he observed, true to type, presented localizations in the axilla, mammae, and pubes, which correspond closely to the sites of predilection in acanthosis nigricans, impetigo herpetiformis, pemphigus vegetans, and erythrasma. The similarity between the localization of the Fox-Fordyce disease and that of pediculi pubis suggested the question whether or not the large sweat glands of the skin might have an etiological relation to the condition. A histological study of Pick's cases showed in the epithelium and papillary layer of the corium the commonly described characteristic changes. The principal changes were found in the deeper layer of the corium, which is almost entirely composed of so-called large and small sweat glands. The changes consisted in inflammatory manifestations in the region of the apocrine sweat glands. The more marked development of these glands in women explains the greater incidence of the condition in the female. There is a different development of these glands in different races. The more frequent occurrence of the condition in America, where mixed races are more common, suggests that a mixture of different races constitutes a basis for increased disposition. As a cause of the condition, a secretory disturbance in the region of the reproductive organs may be postulated. In accordance with this theory, organotherapy, consisting of the administration of ovarian and corpus luteum preparations, was distinctly successful in the two cases which Pick reports, relieving the patients of their suffering which up to that time had persisted in spite of treatment. The recognition of the pathogenesis of the Fox-Fordyce disease thus suggests at once an effective remedy, and makes it evident that the disease is an independent entity, as a result of which it can no longer be classified in the neurodermatitis group.

Radiographic Exploration of the Bronchopulmonary System by Means of Lipiodol—Since in the diagnosis of certain bronchopulmonary conditions it not infrequently happens that the roentgenological study of the chest, as usually carried out, fails to supply adequate and precise information, John Guy and H. C. Elder (*Edinburgh Medical Review*, May, 1926, n. s. xxxiii, 5) suggest the use of lipiodol. A preliminary injection of 1/6 gr. of morphine is given subcutaneously from one-quarter to three-quarters of an hour before

making the lipiodol injection. With the patient in the recumbent position local anesthesia is induced with 2 c.c. of a 2 per cent solution of cocaine over the cricothyroid space, the needle is passed slowly through this membrane and into the submucous lining of the trachea, and then into the lumen of the trachea itself. In making the lipiodol injection of 20 c.c. record syringe, specially modified for the purpose, is employed. In order to facilitate the injection the lipiodol contained is heated in a water-bath (at 50° to 60° C), thereby rendering it less viscid. The needle is thrust perpendicularly into the cricothyroid membrane, and the lumen of the trachea having been reached, a slight upward movement of the syringe enables the needle to slip down the airway in a direction parallel to its walls, thus avoiding injury to the mucosa. When the injection is completed iodine is applied to the puncture wound, no dressing is required. The amount of lipiodol injected varies from 8 to 10 c.c., in children from 7 to 14 years of age, to 30 or 40 in adults. While the injection is being made, it is necessary so to move the patient that the lipiodol will tend to gravitate toward the particular field under investigation. In the vast majority of cases, if reasonable precautions are taken, complications are not likely to arise. In view of the encouraging results thereby obtained in the diagnosis of broncho-pulmonary affections, the authors feel justified in urging more extended application of the procedure.

Action of Eucalyptol on the Bacillus of Tuberculosis in Vitro—Paul Fabry gives a brief account of some experiments carried out in the bacteriological laboratory of the University of Liege. Before he was able to report on his finds, other experimenters stated that the development of the bacillus in question could be arrested with a 0.4 per cent concentration of eucalyptol. The author had found that a much weaker concentration could secure this result. Even the vapor given off by eucalyptol is strong enough for this purpose. A solution of two-tenths per cent strength will hinder the development of the bovine bacillus. In testing the vapor, solid cultures of the bacillus on potato were used. After exposure to the vapor for a given length of time inoculations of guinea pigs with the culture proved negative. The dead cultures inoculated subcutaneously even improved the animals' general condition by a gain in weight. The bacillus of human tuberculosis is not mentioned in the brief report nor are any conclusions drawn as to the use of eucalyptol in clinical tuberculosis of any sort.—*Annales de l'Institut Pasteur*, June, 1926.

This condition was about the same when seen again in October, 1925

During the pendency of this action, the defendant pursuant to procedure, was examined by the plaintiff's attorney before trial, at which time the defendant gave testimony of his examination, diagnosis and treatment of the patient. When the action came on for trial the plaintiff testified in her own behalf. In the course of her testimony she stated that two days after the first treatment a redness appeared over the area which had been treated, that when she received this treatment she was lying on her back on a table, that at the time of the second treatment she was lying in the same position as at the previous treatment. Testimony of physicians was introduced in behalf of the plaintiff, part of which was to the effect that it was not proper and approved practice to give a second X-ray treatment over an area which had been previously treated and which treatment had produced an erythema. The family physician of the plaintiff in testifying in her behalf stated that her condition was one of phlebitis and not fibro sarcoma (although all the other medical testimony was to the contrary). On cross-examination he was shown to be unqualified to testify as to the treatment of such a condition by deep X-ray therapy.

The testimony of the defendant, taken by the plaintiff in the examination before trial, was read on behalf of the plaintiff as part of the

plaintiff's case. At the close of the plaintiff's testimony a motion was made in the defendant's behalf to dismiss the complaint on the ground that the plaintiff had failed to make out a cause of action and had failed to establish that the result complained of was due to any negligence or carelessness upon the part of the defendant in the administration of the X-ray therapy, it having been previously testified by the plaintiff's own witnesses that the factors of dosage used by the defendant were correct. The court, however, denied the defendant's motion and submitted to the jury the question of whether or not the defendant had treated the plaintiff over the area upon which an erythema had appeared. The testimony of the defendant being already in the case by virtue of the reading of the examination before trial, it was concluded not to put in any testimony on behalf of the defendant but rest the defendant's case upon the plaintiff's own testimony, counsel being of the opinion that the plaintiff had failed to make out a cause of action. The jury after an hour and a half's deliberation rendered its verdict in favor of the defendant. They felt great sympathy for the plaintiff and for her pain and suffering, but they further felt and so found that the treatment of the defendant was warranted and justified, that the occurrence of the erythema and the subsequent ulceration was not due to any negligence or carelessness upon his part and they therefore found in the defendant's favor.

ENCEPHALITIS—THIRD DEGREE BURNS OR TROPIC ULCERS

A physician was called to attend a fireman about twenty-six years of age. On examination he found the patient suffering from muscular tremors and pains in the legs, arms and back. He prescribed for external use menthol 1 dram, camphor 5 grains, chloral 1 dram, alcohol 4 ounces, he also prescribed phenacetine, salicylate and iodine and ordered a hot water bag. When he visited the patient on the following day he found the skin on the legs and back red. He then prescribed Burow's solution as a wet dressing. The physician saw the patient daily for about three weeks. A nerve specialist was then called in consultation who diagnosed the patient's ailment as myoclonic polio encephalitis. On the next day the patient was removed to a hospital and received no further treatment from the defendant.

The defendant had used this liniment for external use in a great number of instances and this was the first time that any reaction was caused thereby.

When the patient was last seen by the defendant there was a sloughing of the skin of the abdomen, of his back and thighs. The physician found that the patient was using hot water bot-

tles without a covering, which he thought may have caused the burns or that the ulcers may have been caused by the trophic condition.

Upon a physical examination made several years later the patient was found to have a deep thick red corrugated scar on the groin down the inner side of the left thigh nearly to the knee, also two small ones on the right front of the abdomen near the groin. The scars to the examining physician indicated tissue destruction through all the skin and into the muscle and fascia beneath and were scars of a third degree burn. The examining physician felt that the scar tissue was due to the trophic disturbance of nerves which nourish the skin and which were damaged by the encephalitis or the injury was due to a combination of abnormally sensitive skin caused by the encephalitis, or the injury was due to a combination acting in an abnormal manner on the abnormal tissue.

When the case was about to be reached for trial the plaintiff's attorney not being successful in procuring a settlement, consented to the discontinuance of the action and the action was thereby terminated in favor of the defendant.

medicines except that specifically prescribed. The patient was further instructed not to eat heavily while under treatment and to keep the bowels regular and also instructed to immediately notify the defendant of any irritation, pain or other symptoms that might occur.

When the patient returned for treatment on August 2nd there was no evidence of an X-ray reaction and no complaint of any kind was made by the plaintiff. After the treatment of August 2nd the next call she made on the defendant was August 26th, at which time there was a slight erythema over the lateral portal of the right thigh. She returned again on September 6th and September 26th at which times light treatment was administered over the slightly reddened area. Thereafter the patient was not again seen by the defendant and this action of alleged malpractice was instituted against him in September, 1923.

During the times that the plaintiff was receiving X-ray therapy from the defendant and after this treatment had been completed, she was under the care of her family physician. During the trial when called as a witness for the plaintiff, this physician testified that two days after the first treatment he called upon the plaintiff at her home, found her in bed with a reddened mass on the front of the thigh and a way clear of the phlebitis, that he could see that this was an X-ray burn and it did not involve the old condition, that he ordered her to remain in bed and began treating her by putting on dressings, that the condition became worse, the burn spread until it was about 4x6 inches and sloughed down to the bone, that he has been treating her since that time, a period of over three years, that about a year after the claimed X-ray burn this physician had a quartz lamp set up in the patient's home and gave her daily treatments from this lamp.

Between the latter part of December, 1922, and the middle of March, 1923, the plaintiff became a bed patient at a hospital. At the time she entered the hospital the plaintiff gave a history of having been treated with X-ray to both thighs on July 28, 1922, and one treatment a week later, lasting about two hours and a half, over the lateral aspect of her right thigh, and about three days after this last treatment she claimed that blisters appeared all over behind and on the lower part of her back which would have included areas that were not treated by the X-ray. The plaintiff told them at the hospital that the blisters broke down and ulcerated and that the lump on her thigh was larger than before. She further stated that the physician had made a diagnosis of phlebitis, but gave no history of any injury or infection of the feet or leg to account for phlebitis. Examination at the hospital disclosed an area of ulceration about 7 centimeters square and a diagnosis was made of

X-ray burn indolent and the patient admitted for excision of the ulceration. Examination at the hospital a few days after admission disclosed on the external aspect of the right thigh a raw scar about 10 centimeters and almost square in shape, in the center of which was a superficial ulcer about 4x5 centimeters with grayish indolent base edges. On the following day under a local anaesthesia the ulcer and skin for an area of 1½ centimeters surrounding the ulcer were excised and the wound left wide open. While at the hospital the wound was irrigated and dressed almost daily. Granulations slowly formed along the borders of the wound and in the middle of February, 1923, examination disclosed that the base of the wound was still covered with a heavy slough and it was questionable whether or not the wound could be healed without removing the patient's leg.

By the end of February there was no progress in the appearance of the lesion within the last month. During all of the time the patient was suffering from quite severe pain. About two months after the plaintiff entered the hospital the surgeon, upon examination, found the base of the wound open and separated from the femur by a small margin of tissue. He found that the surface looked better than it did a month previous, which was especially true about the periphery, the pain however being nearly as severe as when the patient entered the hospital. From the time the patient entered the hospital her treatment had consisted of excision of the ulceration, applications of heat both moist and dry followed by escharotic pastes. This examining physician was of the opinion that local treatment should be persisted in, consisting of cleansing, dressings and stimulating applications to the surface for the next few months in an effort to obtain a surface to which skin can be grafted. He was of the further opinion that amputation of the leg at the hip would relieve the patient's pain, but the tissues all about were so affected that primary healing could not be hoped for, and that this procedure would end up in an open wound quite as large as the one then present. Amputation of the limb was not resorted to, the patient refusing to consent to such operation though her general condition remained good.

After the patient left the hospital the local treatment of the ulcerated area was continued at the patient's home. The hospital followed up the condition through its visiting nurses. When seen in April, 1925, by a visiting nurse the plaintiff was still receiving local treatment of dressing, light and ointments. The wound at that time was a little better but gave off a very offensive odor. The plaintiff was up and about and able to do her housework, but could not walk up or down stairs and the patient said she had not been out of the house for about three years.

as having taken control of the activities of three county public health nurses, and Schenectady County to have done excellent work in the organized anti-diphtheria work

The third question "What has been the occasion of its most successful meeting in the last five years?" was answered by Dr J P Henry of Monroe County, who said that in this county it was the testimonial dinner to Dr George Goler on his completion of a service of 27 years as health officer of Rochester (See this JOURNAL, Feb 1, 1926, page 119)

Dr D J Landsman, of Bronx County, said that the most successful meeting of his Society was one in which \$40,000 was subscribed by the doctors toward a building for the Society

Dr A H Brownell, of Oneonta, said that the most successful meeting of the Otsego County Society was that when a dinner was given to two of its members who had been fifty years in the practice of medicine

Dr W B Brooks, of Herkimer County, said that his County had given a dinner to two of its members,—Dr Seuter, Secretary for 52 years, and Dr Graves, Treasurer for 40 years

Dr D A Eiseline of Ontario, claimed that his County was the originator of testimonial dinners to the older members, for it had started the practice in 1904

Dr Fish, of Tompkins, said that the most successful meetings of his Society were the anniversary meetings

Dr L F Schiff, of Clinton County, said that while his County had given testimonial dinners, the real criterion of a successful meeting was its scientific sessions The most successful meeting of his County society was a lecture in the pediatric course when movies of the Barton obstetrical forceps were shown

Questions 4 and 5, regarding post graduate courses, were considered together

Dr G S Skiff, of Wyoming County, said his County had conducted a successful course in pediatrics and obstetrics, and that he hoped that other courses would be given

Dr E N Morgan, of Genesee County, said that the attendance on a post graduate course in his County was poor, and he gave as the reason that the lectures were on subjects of pediatrics and obstetrics, which were specialties He suggested a lecture on the general aspects of syphilis as being more interesting to the members of his County Society

Dr D S Dougherty commented that he supposed the subjects of pediatrics and obstetrics would appeal strongly to the average doctor, because much of the practice of a family doctor consists of confinements and the treatment of babies He quoted Rockland County in which the attendance at Dr Kosmak's talk on Prenatal Care of Mothers was nearly 100 per cent of the physicians of the County

Dr W R Pierce described a successful course on diabetes that was conducted in Montgomery County (See this JOURNAL, August 15th, 1926, page 725)

Dr A H Brownell of Otsego County said that 30 to 35 doctors out of a membership of 42 attended the course in obstetrics and pediatrics, and he said that if any one could suggest another subject as good, it would be adopted in Otsego County

Mr J Neff, lay secretary of the Nassau County Medical Society, said that Nassau County had put on a successful course of six lectures in pediatrics and five in obstetrics because these were the subjects named by the greater number of doctors after a canvass of all the members. One lecture was also given in each of the other subjects that were nominated Over 50 individual members had attended at least one lecture, and 25 members had attended all the lectures The same plan will be followed this year The men will attend what they ask for

Dr J D Carroll described the course that was tried in Rensselaer County The first lecture was well attended, but it was not interesting, and so the members did not turn out to the others

Regarding question 6 "Have you ever tried a program for the meetings of a year?" Dr T M Brennan described the plan of Kings County in which the incoming President, who is nearly always elevated from the Vice Presidency, announces the general plan of the monthly meetings of the Society for the whole year, and makes his arrangements to carry out his plan, it being understood that the meetings for the year are his to arrange

Dr Brennan also described the series of medical lectures which are held on Friday afternoons at 5 o'clock, at which the attendance is limited to four or five hundred, owing to the lack of greater capacity of the meeting room

Dr Fish said that the Tompkins County Society appoints a committee for each meeting of the year, and makes it responsible for the program of that meeting

Regarding question 7 on the comparative values of utilizing local talent, or inviting eminent speakers, Dr W B Brooks of Herkimer said that some men in his County say "I am not interested in what any local man has to say, for he is no better than I am."

Dr D S Dougherty said that the New York County Society had usually found its meetings far more crowded when eminent outsiders were invited to speak than when local talent was employed He said that there were many local medical societies in which local men read papers, but that the county society room was crowded only when eminent men from outside spoke

Dr Peter Noe, Jr, said that he did not have the courage to ask an eminent man to come and

NEWS NOTES

THE SECRETARIES' CONFERENCE

A conference of the Secretaries of the Medical Societies of the Counties of the State of New York was held on Thursday, September 2nd, 1926, in the Hotel Ten Eyck, Albany, pursuant to the authorization of the Council. The Secretaries dined together, and after the luncheon the session was opened by Dr Daniel S Dougherty, Secretary of the Medical Society of the State of New York. Forty counties were represented as follows

Albany, Dr H A Peck, Bronx, Dr T S Landsman, Broome, Dr L H Quackenbush, Cattaraugus, Dr R B Morris, Cayuga, Dr G P Ross, Chautauqua, Dr E Bieber, Clinton, Dr L F Schiff, Cortland, Dr A M Loope, Delaware, Dr W Armistron, Dutchess-Putnam, Dr W F Carpenter, Erie, Dr J B Croff, Essex, Dr Peter Noe, Jr, Genessee, Dr E N Morgan, Greene, Dr W M Raff, Herkimer, Dr W B Brooks, Jefferson, Dr J D Olin, Kings, Dr T M Brennan, Livingston, Dr L A Damon, Madison, Dr D H Conferman, Monroe, Dr J P Henry, Montgomery, Dr W R Pierce, Nassau, Mr J L Neff, Executive Secretary, New York, Dr J M Mabbott, Niagara, Dr G L Miller, Oneida, Dr W Hale, Jr, Onondaga, Dr William J McNerny, Ontario, Dr E A Eiseline, Orleans, Dr John Dugan, Otsego, Dr A M Brownell, Queens, Dr E M Smith, Rensselaer, Dr J D Carroll, Scholiarie, Dr H L Odell, Seneca, Dr J N Frost, Suffolk, Dr Frank Overton, Tompkins, Dr W G Fish, Ulster, Dr F H Voss, Washington, Dr S Pishley, Waynes, Dr D F Johnson, Westchester, Dr Harrison Betts, Wyoming, Dr C B Skiff

The registration card which will be sent to every doctor under the new practice of medicine act was explained by Dr Harold Rypins, Secretary of the Board of Examiners of the Regents of the University of the State of New York (See page 803)

The principal business of the Conference was the discussion of ten points of a questionnaire sheet which each secretary was expected to fill out with data regarding his own Society. These points were the subjects of an animated discussion which lasted for three hours. The questionnaire was as follows

- 1 Is your Society in a healthy condition?
- 2 Has it undertaken any special feature in last five years?
- 3 What has been the occasion of its most successful meeting in this time?

- 4 Which post-graduate courses have you had?
- 5 What post-graduate work would you care to take up next?
- 6 Have you ever tried a program for the meetings of a year?
- 7 Are the men interested in papers or clinics prepared by members?
- 8 What welfare organizations have you invited to send representatives to any of your meetings to explain their programs?
- 9 Function of Comitia Minora
- 10 Miscellaneous subjects—
Workmen's Compensation,
Chiropractic situation,
Support friendly legislators in coming election

The first question "Is your society in a healthy condition?" was answered by Dr W G Fish, of Tompkins, with the counter-question, "What are the standards for measuring the health of a county medical society?"

Dr Harrison Betts of Westchester gave three points of measurement

- 1 Attendance at meetings by fifty per cent of the membership
- 2 Interesting a widening circle of members in the programs of the meetings
- 3 The presentation of papers by the society's own members

Dr Croff, of Erie, said that he thought the Erie County Medical Society was in a healthy condition, although it failed to secure a fifty per cent attendance of its 673 members

Dr E A Eiseline, Secretary of the Ontario County Medical Society for 28 years, said that if the officers want anything and can count on the whole membership to back them up, that Society is in a healthy condition, even if fifty per cent of its members cannot come to a meeting

Dr W Hale, Jr, of Oneida County, said that some phase of county medical society work was usually discussed at the meeting of the hospital staff of his County. Some years ago the younger men of the Society thought that quarterly meetings were not frequent enough, and so they made them bi-monthly, and the attendance continues to average 33 per cent of the membership, as before the change, while 50 per cent attended the annual outing meeting

Dr Hale also suggested a testimonial dinner to all doctors who reach the age of seventy

In regard to the second question "Has your society undertaken any special feature in the last five years?" the Tioga County Society was quoted

as having taken control of the activities of three county public health nurses, and Schenectady County to have done excellent work in the organized anti-diphtheria work.

The third question "What has been the occasion of its most successful meeting in the last five years?" was answered by Dr J P Henry of Monroe County, who said that in this county it was the testimonial dinner to Dr George Goler on his completion of a service of 27 years as health officer of Rochester (See this JOURNAL, Feb 1, 1926, page 119)

Dr D J Landsman, of Bronx County, said that the most successful meeting of his Society was one in which \$40,000 was subscribed by the doctors toward a building for the Society

Dr A H Brownell, of Oneonta, said that the most successful meeting of the Otsego County Society was that when a dinner was given to two of its members who had been fifty years in the practice of medicine

Dr W B Brooks, of Herkimer County, said that his County had given a dinner to two of its members,—Dr Seuter, Secretary for 52 years, and Dr Graves, Treasurer for 40 years

Dr D A Eiseline of Ontario, claimed that his County was the originator of testimonial dinners to the older members, for it had started the practice in 1904

Dr Fish, of Tompkins, said that the most successful meetings of his Society were the anniversary meetings

Dr L F Schiff, of Clinton County, said that while his County had given testimonial dinners, the real criterion of a successful meeting was its scientific sessions. The most successful meeting of his County society was a lecture in the pediatric course when movies of the Barton obstetrical forceps were shown

Questions 4 and 5, regarding post graduate courses, were considered together

Dr G S Skiff, of Wyoming County, said his County had conducted a successful course in pediatrics and obstetrics, and that he hoped that other courses would be given

Dr E N Morgan, of Genesee County, said that the attendance on a post graduate course in his County was poor, and he gave as the reason that the lectures were on subjects of pediatrics and obstetrics, which were specialties. He suggested a lecture on the general aspects of syphilis as being more interesting to the members of his County Society

Dr D S Dougherty commented that he supposed the subjects of pediatrics and obstetrics would appeal strongly to the average doctor, because much of the practice of a family doctor consists of confinements and the treatment of babies. He quoted Rockland County in which the attendance at Dr Kosmak's talk on Prenatal Care of Mothers was nearly 100 per cent of the physicians of the County

Dr W R Pierce described a successful course on diabetes that was conducted in Montgomery County (See this JOURNAL, August 15th, 1926, page 725)

Dr A H Brownell of Otsego County said that 30 to 35 doctors out of a membership of 42 attended the course in obstetrics and pediatrics, and he said that if any one could suggest another subject as good, it would be adopted in Otsego County

Mr J Neff, lay secretary of the Nassau County Medical Society, said that Nassau County had put on a successful course of six lectures in pediatrics and five in obstetrics because these were the subjects named by the greater number of doctors after a canvass of all the members. One lecture was also given in each of the other subjects that were nominated. Over 50 individual members had attended at least one lecture, and 25 members had attended all the lectures. The same plan will be followed this year. The men will attend what they ask for

Dr J D Carroll described the course that was tried in Rensselaer County. The first lecture was well attended, but it was not interesting, and so the members did not turn out to the others

Regarding question 6 "Have you ever tried a program for the meetings of a year?" Dr T M Brennan described the plan of Kings County in which the incoming President, who is nearly always elevated from the Vice Presidency, announces the general plan of the monthly meetings of the Society for the whole year, and makes his arrangements to carry out his plan, it being understood that the meetings for the year are his to arrange

Dr Brennan also described the series of medical lectures which are held on Friday afternoons at 5 o'clock, at which the attendance is limited to four or five hundred, owing to the lack of greater capacity of the meeting room

Dr Fish said that the Tompkins County Society appoints a committee for each meeting of the year, and makes it responsible for the program of that meeting

Regarding question 7 on the comparative values of utilizing local talent, or inviting eminent speakers, Dr W B Brooks of Herkimer said that some men in his County say "I am not interested in what any local man has to say, for he is no better than I am."

Dr D S Dougherty said that the New York County Society had usually found its meetings far more crowded when eminent outsiders were invited to speak than when local talent was employed. He said that there were many local medical societies in which local men read papers, but that the county society room was crowded only when eminent men from outside spoke

Dr Peter Noe, Jr, said that he did not have the courage to ask an eminent man to come and

NEWS NOTES

THE SECRETARIES' CONFERENCE

A conference of the Secretaries of the Medical Societies of the Counties of the State of New York was held on Thursday, September 2nd, 1926, in the Hotel Ten Eyck, Albany, pursuant to the authorization of the Council. The Secretaries dined together, and after the luncheon the session was opened by Dr. Daniel S. Dougherty, Secretary of the Medical Society of the State of New York. Forty counties were represented as follows:

Albany, Dr. H. A. Peck, Bronx, Dr. T. S. Landsman, Broome, Dr. L. H. Quackenbush, Cattaraugus, Dr. R. B. Morris, Cayuga, Dr. G. P. Ross, Chautauqua, Dr. E. Bieber, Clinton, Dr. L. F. Schiff, Cortland, Dr. A. M. Loope, Delaware, Dr. W. Armiston, Dutchess-Putnam, Dr. W. F. Carpenter, Erie, Dr. J. B. Croff, Essex, Dr. Peter Noe, Jr., Genesee, Dr. E. N. Morgan, Greene, Dr. W. M. Raff, Herkimer, Dr. W. B. Brooks, Jefferson, Dr. J. D. Olin, Kings, Dr. T. M. Brennan, Livingston, Dr. L. A. Damon, Madison, Dr. D. H. Conterman, Monroe, Dr. J. P. Henry, Montgomery, Dr. W. R. Pierce, Nassau, Mr. J. L. Neff, Executive Secretary, New York, Dr. J. M. Mabbott, Niagara, Dr. G. L. Miller, Oneida, Dr. W. Hale, Jr., Onondaga, Dr. William J. McNerny, Ontario, Dr. E. A. Eiseline, Orleans, Dr. John Dugan, Otsego, Dr. A. M. Brownell, Queens, Dr. E. M. Smith, Rensselaer, Dr. J. D. Carroll, Schoharie, Dr. H. L. Odell, Seneca, Dr. J. N. Frost, Suffolk, Dr. Frank Overton, Tompkins, Dr. W. G. Fish, Ulster, Dr. F. H. Voss, Washington, Dr. S. Pishley, Wayne, Dr. D. F. Johnson, Westchester, Dr. Harrison Betts, Wyoming, Dr. C. B. Skiff.

The registration card which will be sent to every doctor under the new practice of medicine act was explained by Dr. Harold Rypins, Secretary of the Board of Examiners of the Regents of the University of the State of New York (See page 803).

The principal business of the Conference was the discussion of ten points of a questionnaire sheet which each secretary was expected to fill out with data regarding his own Society. These points were the subjects of an animated discussion which lasted for three hours. The questionnaire was as follows:

- 1 Is your Society in a healthy condition?
- 2 Has it undertaken any special feature in last five years?
- 3 What has been the occasion of its most successful meeting in this time?

- 4 Which post-graduate courses have you had?
- 5 What post-graduate work would you care to take up next?
- 6 Have you ever tried a program for the meetings of a year?
- 7 Are the men interested in papers or clinics prepared by members?
- 8 What welfare organizations have you invited to send representatives to any of your meetings to explain their programs?
- 9 Function of Comitia Minora
- 10 Miscellaneous subjects—
Workmen's Compensation,
Chiropractic situation,
Support friendly legislators in coming election

The first question "Is your society in a healthy condition?" was answered by Dr. W. G. Fish, of Tompkins, with the counter-question, "What are the standards for measuring the health of a county medical society?"

Dr. Harrison Betts of Westchester gave three points of measurement:

- 1 Attendance at meetings by fifty per cent of the membership
- 2 Interesting a widening circle of members in the programs of the meetings
- 3 The presentation of papers by the society's own members

Dr. Croff, of Erie, said that he thought the Erie County Medical Society was in a healthy condition, although it failed to secure a fifty per cent attendance of its 673 members.

Dr. E. A. Eiseline, Secretary of the Ontario County Medical Society for 28 years, said that if the officers want anything and can count on the whole membership to back them up, that Society is in a healthy condition, even if fifty per cent of its members cannot come to a meeting.

Dr. W. Hale, Jr., of Oneida County, said that some phase of county medical society work was usually discussed at the meeting of the hospital staff of his County. Some years ago the younger men of the Society thought that quarterly meetings were not frequent enough, and so they made them bi-monthly, and the attendance continues to average 33 per cent of the membership, as before the change, while 50 per cent attended the annual outing meeting.

Dr. Hale also suggested a testimonial dinner to all doctors who reach the age of seventy.

In regard to the second question "Has your society undertaken any special feature in the last five years?" the Tioga County Society was quoted

as having taken control of the activities of three county public health nurses, and Schenectady County to have done excellent work in the organized anti-diphtheria work.

The third question "What has been the occasion of its most successful meeting in the last five years?" was answered by Dr J P Henry of Monroe County, who said that in this county it was the testimonial dinner to Dr George Goler on his completion of a service of 27 years as health officer of Rochester (See this JOURNAL, Feb 1, 1926, page 119)

Dr D J Landsman, of Bronx County, said that the most successful meeting of his Society was one in which \$40,000 was subscribed by the doctors toward a building for the Society

Dr A H Brownell, of Oneonta, said that the most successful meeting of the Otsego County Society was that when a dinner was given to two of its members who had been fifty years in the practice of medicine

Dr W B Brooks, of Herkimer County, said that his County had given a dinner to two of its members,—Dr Seuter, Secretary for 52 years, and Dr Graves, Treasurer for 40 years

Dr D A Eiseline of Ontario, claimed that his County was the originator of testimonial dinners to the older members, for it had started the practice in 1904

Dr Fish, of Tompkins, said that the most successful meetings of his Society were the anniversary meetings

Dr L F Schiff, of Clinton County, said that while his County had given testimonial dinners, the real criterion of a successful meeting was its scientific sessions. The most successful meeting of his County society was a lecture in the pediatric course when movies of the Barton obstetrical forceps were shown

Questions 4 and 5, regarding post graduate courses, were considered together

Dr G S Skiff, of Wyoming County, said his County had conducted a successful course in pediatrics and obstetrics, and that he hoped that other courses would be given

Dr E N Morgan, of Genesee County, said that the attendance on a post graduate course in his County was poor, and he gave as the reason that the lectures were on subjects of pediatrics and obstetrics, which were specialties. He suggested a lecture on the general aspects of syphilis as being more interesting to the members of his County Society

Dr D S Dougherty commented that he supposed the subjects of pediatrics and obstetrics would appeal strongly to the average doctor, because much of the practice of a family doctor consists of confinements and the treatment of babies. He quoted Rockland County in which the attendance at Dr Kosmak's talk on Prenatal Care of Mothers was nearly 100 per cent of the physicians of the County

Dr W R Pierce described a successful course on diabetes that was conducted in Montgomery County (See this JOURNAL, August 15th, 1926, page 725)

Dr A H Brownell of Otsego County said that 30 to 35 doctors out of a membership of 42 attended the course in obstetrics and pediatrics, and he said that if any one could suggest another subject as good, it would be adopted in Otsego County

Mr J Neff, lay secretary of the Nassau County Medical Society, said that Nassau County had put on a successful course of six lectures in pediatrics and five in obstetrics because these were the subjects named by the greater number of doctors after a canvass of all the members. One lecture was also given in each of the other subjects that were nominated. Over 50 individual members had attended at least one lecture, and 25 members had attended all the lectures. The same plan will be followed this year. The men will attend what they ask for

Dr J D Carroll described the course that was tried in Rensselaer County. The first lecture was well attended, but it was not interesting, and so the members did not turn out to the others

Regarding question 6 "Have you ever tried a program for the meetings of a year?" Dr T M Brennan described the plan of Kings County in which the incoming President, who is nearly always elevated from the Vice Presidency, announces the general plan of the monthly meetings of the Society for the whole year, and makes his arrangements to carry out his plan, it being understood that the meetings for the year are his to arrange

Dr Brennan also described the series of medical lectures which are held on Friday afternoons at 5 o'clock, at which the attendance is limited to four or five hundred, owing to the lack of greater capacity of the meeting room

Dr Fish said that the Tompkins County Society appoints a committee for each meeting of the year, and makes it responsible for the program of that meeting

Regarding question 7 on the comparative values of utilizing local talent, or inviting eminent speakers, Dr W B Brooks of Herkimer said that some men in his County say "I am not interested in what any local man has to say, for he is no better than I am"

Dr D S Dougherty said that the New York County Society had usually found its meetings far more crowded when eminent outsiders were invited to speak than when local talent was employed. He said that there were many local medical societies in which local men read papers, but that the county society room was crowded only when eminent men from outside spoke

Dr Peter Noe, Jr, said that he did not have the courage to ask an eminent man to come and

address the Essex County Medical Society which has only 24 members

Dr J B Croff suggested that the business part of a meeting be made short so as to give the speakers a fair show

He also suggested that other topics besides medicine be discussed—workmen's compensation for example, or the medical practice act. He also found a collation to be an incentive to attendance or to staying through a meeting

Dr Dougherty said that the New York County Society transacted its business through a large Comitia Minora, for experience had shown that the members would not stay through a business session—they preferred that the elected officers should attend to all the details of business affairs

Question 8 was, "What welfare organizations have you invited to send representatives to any of your meetings to explain their programs?" brought out a series of "noes" for answers. Dr McNerney of Onondaga County said that the members of Onondaga County come together solely for the scientific program

It seemed to be the opinion of several speakers that the members had heard so much about public health that they were surfeited with it

Dr Dougherty described the work of the New York County Society in promoting periodic health examinations

Dr Frank Overton said that the Suffolk County Medical Society dominated and led the county tuberculosis committee and that it always invited members of that and other welfare organizations to attend the meetings

Dr J F Schiff said that the Clinton County Medical Society had invited the public health nurses to take part in the program of one meeting, but that the experiment would not be repeated, for it led to misunderstandings and disputes. He said that a better plan would be to let a committee of the society deal with the welfare workers, and that the committee should make reports to the society with recommendations. He said that in counties where this was done, co-

operation of the medical and lay organizations was secured

Regarding the function of the Comitia Minora—question 9—Dr J M Mabbott suggested that one function might well be to guide the elections so that competent officers were chosen

Reference was made to question 10 by Dr Henry L K Shaw, Chairman of the Committee on Legislation, when he said that medical legislation was by no means ended with the passage of the Practice of Medicine Act. Medical topics would have an increasingly important place in legislation, and the subject of industrial medicine will probably be brought prominently before the next legislature

Dr George M Fisher, President of the Medical Society of the State of New York, closed the discussion with comments on some of the points which had been brought out

Regarding Post Graduate Education, he was surprised to hear that a rural society should prefer the subject of syphilis to pediatrics and obstetrics, but if a society wanted to study syphilis, the State Society should supply the teacher

Regarding welfare organizations, Dr Fisher suggested that if the leader of a welfare organization asked for advice, the doctors should give it to them, but should not turn the matter entirely over to them. A doctor should treat a case whether it was brought by a nurse or not. He commended the mental clinic of Utica, in which on one day eight cases were examined, all brought by doctors. This benefited the patients, the doctors, and the community

Dr Fisher urged the physicians to do preventive diphtheria work in the families which they have on their visiting lists. He also commended the social side of organizations of doctors

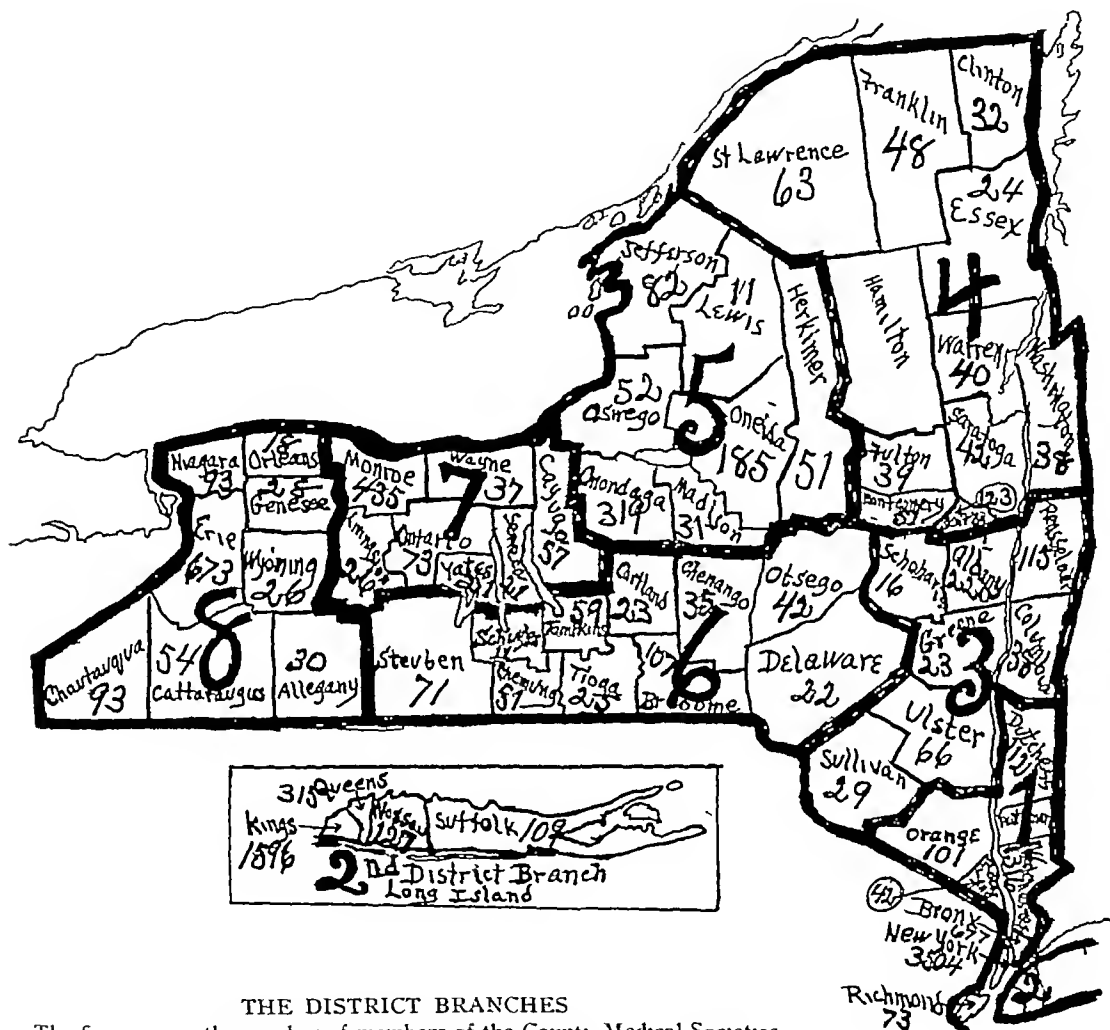

The unanimous impression of those attending the conference was that it was well worth holding. The discussions were brief, snappy, and to the point, and were given almost entirely by the secretaries. It was an experience meeting, and the opinions expressed will be of great value to the County Secretaries and to the officers of the State Society

DISTRICT BRANCH MEETINGS

The following dates and places for the meetings of the District Branches have been announced
 Tuesday, September 21, *Sixth*, in Owego
 Saturday, September 25, *Third*, in Albany
 Wednesday, September 29, *Seventh*, in Geneva

Friday, October 1, *Fourth*, in Plattsburg
 Thursday, October 14, *Fifth*, in Watertown
 Wednesday and Thursday, October 27 and 28, *Eighth*, in Buffalo
 Wednesday, November 10, *First*, in Briarcliff

daries of the districts, and the names of the officers. This information is supplied in this article and the accompanying map.

The figures give the number of members of the County Medical Societies

President—Charles P McCabe, M D, Greenville.
1st Vice-President—Edgar A Vander Veer
M D, Albany
2nd Vice-President—Herbert L Odell, M D,
Sharon Springs
Secretary—Clark G Rossman, M D, Hudson
Treasurer—Ernest E Billings, M D, Kingston

Fourth District Branch

President—Horace M Hicks, M D, Amsterdam
 1st Vice-President—Lyman G Barton, M D, Plattsburg
 2nd Vice-President—William L Munson, M D, Granville
 Secretary—Carl R Comstock, M D, Saratoga Springs
 Treasurer—Sidney F Blanchet, M D, Saranac Lake

Fifth District Branch

President—Charles D Post, M D, Syracuse
 1st Vice-President—Page E Thornhill, M D, Watertown
 2nd Vice-President—Augustus B Santry, M D, Little Falls
 Secretary—William J McNeerney, M D, Syracuse
 Treasurer—Frank E Fox, M D, Fulton

Sixth District Branch

President—Wilbur G Fish, M D, Ithaca
 1st Vice-President—LaRue Colgrove, M D, Elmira
 2nd Vice-President—George M Cady, M D, Owego

Secretary—Hubert B Marvin, M D, Binghamton
 Treasurer—Stuart B Blakely, M D, Binghamton

Seventh District Branch

President—Claude C Lytle, M D, Geneva
 1st Vice-President—G Kirby Collier, M D, Rochester
 2nd Vice-President—A W Armstrong, M D, Canandaigua
 Secretary—John A Lichty, M D, Clifton Springs
 Treasurer—Edward T Wentworth, M D, Rochester

Eighth District Branch

President—George W Cottis, M D, Jamestown
 1st Vice-President—Thomas J Walsh, M D, Buffalo
 2nd Vice-President—Francis E Fronczak, M D, Buffalo
 Secretary—W Warren Britt, M D, Tonawanda
 Assist Secretary—Russell H Wilcox, M D, Tonawanda
 Treasurer—Fitch H Van Orsdale, M D, Belmont

THE GRIEVANCE COMMITTEE

A meeting of the Grievance Committee that was appointed under the recent Medical Practice Act was held in Albany at the Department of Education on September 2, 1926, and was opened by Dr August S Downing, Deputy Commissioner of Education. All the members of the Committee were present, as follows

Frederick H Flaherty, M D, Syracuse
 Allan A Jones, M D, Rochester
 Moses Keschner, M D, New York
 Grant C Madill, M D, Ogdensburg
 William S Overton, M D, Binghamton
 Martin B Tinker, M D, Ithaca
 Roy Upham, M D, Brooklyn
 Arthur B Van Loon, M D, Albany
 Orrin Sage Wightman, M D, New York
 Ralph Williams, M D, Rochester

As the main purpose of coming together was organization, the first order of business was the election of a permanent Chairman and a Secretary. Dr Orrin Sage Wightman of New York was duly elected Chairman and Dr Frederick H Flaherty of Syracuse, Secretary.

The committee felt that the work of the committee could be best served by the appointment of a sub-committee so located in the State that they could readily come together and review

reference cases coming within their local areas. The findings of these sub-committees would automatically be referred to the whole committee, if the cases were not otherwise settled. To make this plan effective the following groups of sub-committees were approved and appointed.

A Western group formed of Dr A A Jones of Buffalo, Dr Ralph Williams of Rochester, and Dr M B Tinker of Ithaca.

A Mid-State group composed of Dr G C Madill of Ogdensburg, Dr F H Flaherty of Syracuse, and Dr W S Overton of Binghamton.

An East-Central group composed of Dr Van Loon of Albany, Dr F H Flaherty of Syracuse, and Dr W S Overton of Binghamton or Dr G C Madill of Ogdensburg.

A Southern group composed of Dr O S Wightman and Dr M Keschner of New York and Dr R. Upham of Brooklyn.

In the event of any man being unable to attend a sub-committee meeting, another man from an adjoining group would attend in his place.

Naturally the work of this Committee will be arduous, but the seriousness of the task and the desire of the whole group to prove worthy of the trust imposed will be an added spur toward putting an end to charlatanism in the State.

ANNUAL REGISTRATION BLANKS

The cards on which physicians are to make application for their first annual registration, under the revised Practice of Medicine Act, are ready for distribution, and will be sent to every physician before October 1. The application card for physicians is as follows:

MEDICINE

Name _____
Address _____ St _____ City or village _____

Applies for Annual Registration as a practitioner of Medicine and affirm under oath that the statements made in this application are true to the best of his knowledge and belief

Place and date of birth _____

Number and date of license _____

License originally recorded in _____ county in year _____

County in which you are now practising _____

M D

Sworn to before me this _____ day of _____ 1926

Notary Public for _____ county

This card with the fee of \$2 must be filled out and returned at once to The University of the State of New York at Albany

[OVER]

DEAR DOCTOR Chapter 834 of the Laws of 1926 requires every practising physician to register annually on or before the first of January of each year with the Board of Regents. Kindly fill out this application blank, have it certified by a notary and return it together with statutory fee of \$2 to the Finance Division of The University of the State of New York, Albany. Make checks payable to The University of the State of New York.

HAROLD RYPINS, M D, *Secretary*
State Board of Medical Examiners

The word license is explained by Dr. Harold Rypins, Secretary to the Board of Medical Examiners, to mean the authority on which the physician bases his right to practice medicine. It may be a license issued by a County Medical Society under the Act of 1806 (one or two doctors who secured their licenses in that way are still living), a diploma granted by a medical school previous to 1893, or a license granted by the University of the State of New York in 1893 or later.

The number of a license previous to 1893 may be difficult or impossible to obtain. If no number is recorded on the license, of course none can be given on the application card. But the licenses issued since 1893 bear numbers.

The final act by which a physician secured the right to practice medicine was that of registration in some county of New York State. The record of that registration is written or stamped on the doctor's diploma. The first registration was made in many instances in the County of New York or Kings, while the doctors were hospital internes. It is the *first* registration that is called for by the card. Subsequent registrations by the clerks of other counties are simply indorsements of the first one.

According to Dr. Rypins, "These applications must be in not later than January 1, but the Department would greatly appreciate the co-operation of the profession in order that the first certified list of duly licensed and registered physicians may be printed and distributed early in January. This list of registered physicians will be mailed to every physician who has registered. The compilation of an accurate list of duly qualified practitioners is a tremendous task and the Department of Education bespeaks the sympathetic cooperation of the medical profession in facilitating this important work."

The Civil Service Commission has completed a list of medical inspectors who will be appointed and who will go on duty some time in September. The Board of Medical Examiners is ready to receive information regarding illegal acts of the practice of medicine, especially the display of signs bearing the word doctor.

The Attorney General has assigned Deputy Attorney Generals George W. Davis and William B. Groat to conduct all prosecutions under the Practice of Medicine Act.

The Chiropractic-Naturopathic Association attempted to bring an injunction against the State officials restraining them from carrying out the provisions of the Act. The suit was brought before a Federal Court, for it involved the State of New York, but Judge Mack denounced the application on the ground of lack of jurisdiction.

All necessary preparations have now been made for putting the Practice of Medicine Act into operation. The indications are that physicians will do their part promptly.

THE DAILY PRESS

EXTRA-TERRITORIALITY

Those who uphold the insistence of Europeans on maintaining their own government and courts in foreign lands will find its justification on hygienic grounds in an editorial from the *New York Herald-Tribune* of August 13th describing conditions in Shanghai, where a thousand Chinese are dying daily of cholera in the old city, and none in the new. The editorial says:

"To understand the significance of these figures and their bearing upon the question of foreign concessions in China it is necessary to recall the origin of the Shanghai 'settlement.' There was a huge Chinese city on the Woosung long before the foreigner came. When, in 1843, the port was opened to foreign trade, the foreigners found its population living under conditions which would have meant early death for Europeans. They asked for an allotment of land where they could build houses and streets after their own kind, and the Chinese assigned the swamplands along the river bank below the city. The worth-

less marsh was considered quite good enough for the foreigner.

"The foreigners accepted the land assigned, and upon it during the succeeding fourscore years they have built a magnificent modern city, whose broad avenues and towering buildings quite overshadow the old Chinese metropolis. The Chinese themselves have not been slow to seek the advantages of the foreign settlement, and they have moved into it by thousands, so that to-day about 90 per cent of its inhabitants are Chinese.

"During all of these years, despite the influx of Chinese, the foreigners have kept the municipal administration in their own hands. Sanitation, roads and streets and police protection have been rigorously kept up to foreign standards. It is only necessary to look at the surrounding towns, at the native city of Shanghai itself, and the conditions which prevail there under Chinese administration, to see why the foreigners living in the settlement insist upon retaining their control."

THE RIGHT TO BE A FOOL

The current notion of American independence is that each individual has the right to take chances with health and safety, to burn up his own property if he wishes, and even to commit suicide. The ground of this reasoning is that each person's property, life or health is his own, to do with it as he pleases. This is the reasoning of the solitary cave man, and does not apply to modern life with its wide ramifications and complications. There is one class of persons whom modern recklessness and license affect seriously, and that is the group of physicians. On them falls the burden of life saving and body mending. The same persons that claim a right to be reckless with health and life, also demand the services of doctors when they are injured. Take, for example, the matter of relief after automobile accidents. Reckless drivers take chances with safety the more readily because they carry accident insurance, and when they are injured, they demand the best medical services from physicians and hospitals, and then when they are healed, they dismiss the matter of pay with the remark "The insurance company will pay the bill." But will the insurance company settle? It will not, for it takes the ground that the accident was due to the autoist's own carelessness, and the doctor and hospital are out of pocket. So notorious has

this condition become that many doctors go to great lengths to avoid treating the victims of automobile accidents.

But not all automobile drivers are careless,—in fact most drivers are careful. On the other hand not all pedestrians who cross the streets are careful,—in fact many are foolishly careless. They act as if they owned the road, as they complacently saunter in front of the oncoming auto, that has the right of way.

It is rarely that a pedestrian is arrested in this country for being injured by an automobile, but such a thing happens in France. The *New York Herald-Tribune* of September 7th has an editorial on "The right to be a cussed fool," which says:

"America, or at least that portion of it which lies between the Hudson and the Delaware, is obviously disinclined to concede that 'they order this matter better in France.' For a long time, indeed, the latter country has enjoyed a unique distinction in dealing with highway accidents, in arresting and punishing the pedestrian who is run down, instead of the driver of the vehicle that runs him down. We should hesitate to compute how many volumes of witticisms and bantering comments have been based upon that anomalous

practice, in which France has commonly been esteemed to be unapproachable

"Suppose that in the exercise of that inalienable right the life, liberty and pursuit of happiness of others are involved? Has the pedestrian a right to get run over and thus cause an uncomfortable jolt to the vehicle that passes over him, to say nothing of the interruption and delay of traffic while his more or less bruised and mangled person is being removed from the highway to the hospital? And has even the smartest of Smart Alecks a right to exploit his foolishness by going out through an obviously dangerous surf and then howling for help and putting others to the labor and peril of going to his relief?"

"It is a complicated problem, at the solution of which we would no trashily leap. There is at every turn a fresh envisioning of Charles Reade's apophthegm, 'There is nothing so inscrutable as a fool'."

The editor then cites a unique example of New Jersey justice which has considerable reputation for promptness and justice

"New Jersey proceeds to demonstrate herself at least nip and tuck with France. One of her municipal magistrates on seeing a swimmer rescued by a lifeguard and safely brought from out the boisterous surf, promptly places the swimmer under arrest as an offender against the peace and dignity of the commonwealth for the atrocious crime of getting nearly drowned."

A news item in another part of the *Tribune* says that after being given a reprimand the defendant was discharged because, although he had violated the dictum of common sense, no New Jersey law seemed to have been broken

A doctor is interested in these cases, for to him comes both the urgent call for first aid and the laggard pay check for his services

WHY QUACKS FLOURISH

Dr Cadman, in his *Daily Counsel* column of the *New York Herald-Tribune* of August 25, undertakes to answer the question "Why is it that, with all our boasted smartness as a nation, quacks of every kind thrive in the United States?" Dr Cadman replies "First, because many Americans are insatiably curious—interrogation points incarnate. Nor could we be a highly inventive people without assuming the risks of questioning and experimentation. Whatever has bite in it or adventure or aggression, with a dash of danger or of mystery, is attractive to our people. In the phrase of the street, they will 'try anything once'."

'Second, because in the American character, which is not yet sufficiently unified to be described, there is a standing conflict between sentimental idealism and ruthless realism. Its peculiar blend of simplicity and shrewdness is its charm and its peril.

'Business men and intelligent women who insist on accuracy and hardheaded judgment for the material side of life will often commit the

care of their physical and mental health to unqualified cranks or fakes. They are willing to be gulled so long as the process is pleasurable.

"In the third place, if Americans are anything they are optimistic. That which feeds hope is welcome, because hope is far easier to practice than the fortitude which faces facts. Moreover, in our land, thick with opportunities, the flattering tales which hope tells are occasionally vindicated. So many who are critical to a fault in other affairs patronize the quack because they or their loved ones are desperately ill, or else they are deeply in love, or, again, crave power in social life or success in business.

"Last, the fool is always abroad in the land. The moronic mind is the quack's green pasture."

Dr Cadman has been a consistent upholder of the practice of scientific medicine and his writings doubtless contributed materially to the creation of public sentiment which resulted in the passage of the Practice of Medicine Act last spring

ADVERTISING ELECTRONIC HEALING

The exponents of the electronic vibration theory of therapeutics have announced that their theory applies to seeds as well as to human beings. A news item in the *New York Herald-Tribune* of September 7 says

"Having succeeded in measuring the vitality of hundreds of unsprouted bean seeds by means of a delicate vibratory machine, members of the American Electronic Research Association are

making tests of other plant life in the laboratories of the McManis College of Electronic Medicine at Kirksville, Mo. Experiments now are being conducted with wheat, corn and oats."

This propaganda is evidently intended to catch the patronage of farmers. It may also be a bid for the farm journals to accept the advertisements of the electronic healers.

THE DAILY PRESS

EXTRA-TERRITORIALITY

Those who uphold the insistence of Europeans on maintaining their own government and courts in foreign lands will find its justification on hygienic grounds in an editorial from the *New York Herald-Tribune* of August 13th describing conditions in Shanghai, where a thousand Chinese are dying daily of cholera in the old city, and none in the new. The editorial says

"To understand the significance of these figures and their bearing upon the question of foreign concessions in China it is necessary to recall the origin of the Shanghai 'settlement.' There was a huge Chinese city on the Woosung long before the foreigner came. When, in 1843, the port was opened to foreign trade, the foreigners found its population living under conditions which would have meant early death for Europeans. They asked for an allotment of land where they could build houses and streets after their own kind, and the Chinese assigned the swamplands along the river bank below the city. The worth-

less marsh was considered quite good enough for the foreigner.

"The foreigners accepted the land assigned, and upon it during the succeeding fourscore years they have built a magnificent modern city, whose broad avenues and towering buildings quite overshadow the old Chinese metropolis. The Chinese themselves have not been slow to seek the advantages of the foreign settlement, and they have moved into it by thousands, so that to-day about 90 per cent of its inhabitants are Chinese.

"During all of these years, despite the influx of Chinese, the foreigners have kept the municipal administration in their own hands. Sanitation, roads and streets and police protection have been rigorously kept up to foreign standards. It is only necessary to look at the surrounding towns, at the native city of Shanghai itself, and the conditions which prevail there under Chinese administration, to see why the foreigners living in the settlement insist upon retaining their control."

THE RIGHT TO BE A FOOL

The current notion of American independence is that each individual has the right to take chances with health and safety, to burn up his own property if he wishes, and even to commit suicide. The ground of this reasoning is that each person's property, life or health is his own, to do with it as he pleases. This is the reasoning of the solitary cave man, and does not apply to modern life with its wide ramifications and complications. There is one class of persons whom modern recklessness and license affect seriously, and that is the group of physicians. On them falls the burden of life saving and body mending. The same persons that claim a right to be reckless with health and life, also demand the services of doctors when they are injured. Take, for example, the matter of relief after automobile accidents. Reckless drivers take chances with safety the more readily because they carry accident insurance, and when they are injured, they demand the best medical services from physicians and hospitals, and then when they are healed, they dismiss the matter of pay with the remark "The insurance company will pay the bill." But will the insurance company settle? It will not, for it takes the ground that the accident was due to the autoist's own carelessness, and the doctor and hospital are out of pocket. So notorious has

this condition become that many doctors go to great lengths to avoid treating the victims of automobile accidents.

But not all automobile drivers are careless,—in fact most drivers are careful. On the other hand not all pedestrians who cross the streets are careful,—in fact many are foolishly careless. They act as if they owned the road, as they complacently saunter in front of the oncoming auto, that has the right of way.

It is rarely that a pedestrian is arrested in this country for being injured by an automobile, but such a thing happens in France. The *New York Herald-Tribune* of September 7th has an editorial on "The right to be a cussed fool," which says

"America, or at least that portion of it which lies between the Hudson and the Delaware, is obviously disinclined to concede that 'they order this matter better in France.' SUBDELTOID BURSTITIS

By MORRIS B COOPERMAN, M D, PHILADELPHIA, PA

SUBDELTOID bursitis, by and large, is unquestionably the most frequent cause of the painful shoulder and should always be thought of first in the diagnosis of that complaint.

There are two diseases with which it is most frequently confused, namely, brachial neuritis and rheumatism. In brachial neuritis, motor, sensory and trophic symptoms appear early and are quite pronounced. In subdeltoid bursitis, the symptoms of nerve implication appear late. Deltoid atrophy, sensory and motor signs, in the hand and fingers, are usually seen late in the subacute or chronic stage of this affection. In brachial neuritis, there is an absence of the cardinal symptoms of subdeltoid bursitis, namely, swelling of the bursa, limitation of abduction and rotation of the shoulder and points of tenderness over the tuberosities. Finally the X-ray evidence of calcified deposits is conclusive that the condition is one referable to the shoulder, rather than to an inflammatory process in the nerve supply of the shoulder.

Rheumatism is a diagnosis which appears to satisfy the conscience of many physicians and is conclusive to the patient. As a matter of fact, there are very few unilateral joint infections, if any, which are really rheumatic in nature. In the absence of symptoms in other joints in the body, it would appear unreasonable to consider rheumatism and in this connection, I might say, that it is a term that is being used less frequently by well informed physicians.

Etiology—The subdeltoid bursa, because of its exposed position, is peculiarly liable to injury and inflammation. Located between the acromion process above and the greater tuberosity beneath and covered by the powerful deltoid muscle, this bursal sac is subjected to compression when the arm is abducted. This applies to the subjacent structures as well, for immediately beneath the floor of the bursal sac are the infra and supra spinati tendons, inserted into the greater tuberosity of the humerus. These also suffer

to a considerable extent. Very frequently, at operations, lacerations have been observed in these tendons, undoubtedly of traumatic origin.

Those who are engaged in certain occupations where the arm is raised above the head a great deal, in certain sports, such as baseball, tennis, etc., or even certain positions while lying in bed, or those who might receive direct blows upon the shoulder or those who might fall upon the outstretched hand, all these will produce compression and contusion of this bursal sac and underlying tendons between these two bony prominences. I have also noticed that two or three weeks after recovery from a wrist fracture, which had been sustained by a fall upon the outstretched hand, there were undoubted evidences of subdeltoid bursitis.

Exposure to wet and cold is also one of the causes of this disease which I have observed, particularly in the case of women who wear such thin clothing.

The relation between focal infection and subdeltoid bursitis has not been established. Bacteriologic examinations of the tissues, removed at operation, fail to reveal any organism. Brickner, in over two hundred cases, failed to note any coexistent infection, tonsillar or otherwise. These cases never suppurate. The deposit, frequently seen beneath the bursal floor, if it be in the liquid state, looks like pus. On its examination, no pus however is found, but fat cells, lime salts and debris.

From a therapeutic standpoint, these findings point to the futility of expecting cures by eradicating suspicious foci of infection.

In my experience, I have frequently advised removal of infected tonsils and teeth, but in most cases, their removal failed to influence the symptomatology.

Some authorities believe that in many of these patients there appears to be a metabolic predisposition to a deposit of lime salts in this region, but what this metabolic fault is, is left to conjecture and speculation. I have

BOOK REVIEWS

DISEASES OF THE NEW-BORN A Monographic Handbook. By JOHN A. FOOTE, M.D. Octavo of 231 pages with illustrations Philadelphia and London, J. B. Lippincott Company, 1926 Cloth, \$5.00

The reviewer's first reaction on picking up this book was that it was unnecessary inasmuch as the subject was adequately covered in the books on the management and treatment of children in general. This may be true, but at least we have read the book with enjoyment. It is well written and it is convenient to have this particular part of childhood treated by itself.

The chapter on therapeutic technique particularly is very convenient and helpful, the reviewer agrees with the space and emphasis devoted to hemorrhage. The book can be safely recommended. W. D. L.

PUBLIC HEALTH LAW A Manual of Law for Sanitarians. By JAMES A. TOBEY, M.S., LL.B. Octavo of 304 pages. Baltimore. Williams and Wilkins Company, 1926 Cloth, \$4.50

The author has presented to those interested in health administration information on the legal aspects of public health which will be found of great value and interest. Health officers will find Mr. Tobey's work of immense value, although, as he states, he does not offer it to take the place of an attorney. E. H. M.

HANDBOOK OF DISEASES OF THE RECTUM By LOUIS J. HIRSCHMAN, M.D., F.A.C.S. Fourth Edition revised and rewritten. Octavo of 403 pages, with illustrations. St. Louis, C. V. Mosby Company, 1926 Cloth, \$6.50

The author states in his preface that the object of this book is to simplify the diagnosis and treatment of many of the more common diseases of the rectum and anus. This has been accomplished in a way that leaves little to be desired. In a simple, practical and yet thorough way the author has discussed all of the usual and more important diseases of this region.

This last edition is slightly larger than the previous one. There are 252 illustrations and 5 beautiful colored plates. Some of the illustrations are new while others were used in the earlier editions.

A symptom index of great value has been introduced. The chapter on Local and Sacral Anaesthesia is new and has been placed near the front of the volume which well illustrates the importance that this method of anesthesia has in all anal and rectal operations.

One sentence must be quoted in toto "Physicians no longer study to discover the type of disease a patient has but rather try to find out what kind of a patient the disease has."

This edition shows the improvement that conscientious work can make in an already good book.

HENRY F. GRAHAM

PURPERAL SEPTICAEMIA Its Causations, Symptoms, Prevention and Treatment. Being the Substance of a Thesis Submitted to the Royal Society of Medicine in June, 1924 and awarded the Nicholls Prize. By GEORGE GEDDES, M.D., CM. (Aber). Octavo of 200 pages. New York. William Wood and Company. 1925. Cloth, \$4.00

This English essay is a most carefully detailed and searching study into the incidence of puerperal fever. Geddes' statistics prove that septicaemia is more common in medical practice than in the cases handled by midwives. With this as a basis he shows that industrial accidents determine the puerperal fever rate in every dis-

trict studied. In other words, medical practitioners, dressing the infected wounds of industry, carry the infection to the woman in labor. His conclusions seem reasonable and should apply to puerperal sepsis everywhere.

His treatment is most radical, consisting in general of a careful search of the true cause for evidence of trauma or infection with the direct application of antiseptics and active surgical removal of infected tissue by curettage.

Decidedly taking issue with our usual modern practice of watchful conservatism, the book is very stimulating. C. A. G.

CAESAREAN SECTION With a Table of 120 Cases. By HERBERT R. SPENCER, M.D., B.S., F.R.C.P. Octavo of 71 pages. New York, William Wood and Company, 1925. Cloth, \$2.75

This little volume of 70 pages is a complete record of all the author's Caesarean sections (120) with a critical analysis of the well known debatable points involved. He condemns catgut sutures and considers the use of specially prepared silk of great importance in the prevention of secondary rupture of the uterine scar. He sees no reason for the present popularity of the low cervical section, and strongly condemns sterilization during the course of Caesarean section as an absolutely and always unjustifiable procedure. A very frank contribution to the subject, it will be read with great interest by American obstetricians. C. A. G.

LACTOBACILLUS ACIDOPHILUS By NICHOLAS KOPELOFF. Ph.D. Octavo of 211 pages. Baltimore, Williams and Wilkins Company, 1926. Cloth, \$5.00

This volume of 200 pages outlines the history, progress, and clinical interpretation of the use and preparation of the *Lactobacillus acidophilus*. The volume is full of interest and affords a clear interpretation as to the manner of preparation and use of this important therapeutic agent. H. M. F.

BERGEY'S MANUAL OF DETERMINATIVE BACTERIOLOGY A Key for the Identification of Organisms of the Class Schizomycetes. By DAVID H. BERGEY. Second Edition. Octavo of 462 pages. Baltimore, Williams and Wilkins Company, 1925. Cloth, \$5.50

This is the second edition of the standard classification of bacteria with the assistance of a committee of the Society of American Bacteriologists.

It is a scientific, biological classification of orders, families, tribes, etc., up to date, and with a rearrangement of keys to make tracing of known species easy. It should be included in the library of every bacteriologist and laboratory. I. COHN

NOUVEAU TRAITÉ DE MÉDECINE. Published under the Direction of G. H. ROGER, FERNAND WIDAL and P. J. TEISSIER. Fascicule XIX. Pathologie du Cerveau et du Cervelet. Octavo of 1016 pages, with illustrations. Paris, Masson et Cie, 1925. Boards 75 francs

This is indeed a splendid volume. It is a reliable monograph that includes the recent advances in our knowledge of the diseases of the cerebrum and cerebellum. There is also a section on labyrinthine syndromes. The illustrations are profuse and well chosen. The motion picture representations of gait and other motor disturbances are particularly instructive. The only fault to be found with this book is the absence of an index, a common defect with our contributions from France. FREDERIC DAMRAU

SUBDELTOID BURSTITIS

By MORRIS B COOPERMAN, M D, PHILADELPHIA, PA.

SUBDELTOID bursitis, by and large, is unquestionably the most frequent cause of the painful shoulder and should always be thought of first in the diagnosis of that complaint.

There are two diseases with which it is most frequently confused, namely, brachial neuritis and rheumatism. In brachial neuritis, motor, sensory and trophic symptoms appear early and are quite pronounced. In subdeltoid bursitis, the symptoms of nerve implication appear late. Deltoid atrophy, sensory and motor signs, in the hand and fingers, are usually seen late in the subacute or chronic stage of this affection. In brachial neuritis, there is an absence of the cardinal symptoms of subdeltoid bursitis, namely, swelling of the bursa, limitation of abduction and rotation of the shoulder and points of tenderness over the tuberosities. Finally the X-ray evidence of calcified deposits is conclusive that the condition is one referable to the shoulder, rather than to an inflammatory process in the nerve supply of the shoulder.

Rheumatism is a diagnosis which appears to satisfy the conscience of many physicians and is conclusive to the patient. As a matter of fact, there are very few unilateral joint infections, if any, which are really rheumatic in nature. In the absence of symptoms in other joints in the body, it would appear unreasonable to consider rheumatism and in this connection, I might say, that it is a term that is being used less frequently by well informed physicians.

Etiology—The subdeltoid bursa, because of its exposed position, is peculiarly liable to injury and inflammation. Located between the acromion process above and the greater tuberosity beneath and covered by the powerful deltoid muscle, this bursal sac is subjected to compression when the arm is abducted. This applies to the subjacent structures as well, for immediately beneath the floor of the bursal sac are the infra and supra spinati tendons, inserted into the greater tuberosity of the humerus. These also suffer

to a considerable extent. Very frequently, at operations, lacerations have been observed in these tendons, undoubtedly of traumatic origin.

Those who are engaged in certain occupations where the arm is raised above the head a great deal, in certain sports, such as baseball, tennis, etc., or even certain positions while lying in bed, or those who might receive direct blows upon the shoulder or those who might fall upon the outstretched hand, all these will produce compression and contusion of this bursal sac and underlying tendons between these two bony prominences. I have also noticed that two or three weeks after recovery from a wrist fracture, which had been sustained by a fall upon the outstretched hand, there were undoubted evidences of subdeltoid bursitis.

Exposure to wet and cold is also one of the causes of this disease which I have observed, particularly in the case of women who wear such thin clothing.

The relation between focal infection and subdeltoid bursitis has not been established. Bacteriologic examinations of the tissues, removed at operation, fail to reveal any organism. Brickner, in over two hundred cases, failed to note any coexistent infection, tonsillar or otherwise. These cases never suppurate. The deposit, frequently seen beneath the bursal floor, if it be in the liquid state, looks like pus. On its examination, no pus however is found, but fat cells, lime salts and debris.

From a therapeutic standpoint, these findings point to the futility of expecting cures by eradicating suspicious foci of infection.

In my experience, I have frequently advised removal of infected tonsils and teeth, but in most cases, their removal failed to influence the symptomatology.

Some authorities believe that in many of these patients there appears to be a metabolic predisposition to a deposit of lime salts in this region, but what this metabolic fault is, is left to conjecture and speculation. I have

observed this disease most frequently in adults between the ages of 35 and 60

Symptoms—The cardinal symptoms of acute subdeltoid bursitis are pain in the shoulder,

FIG 1—Case 4 Shows a large calcific deposit capping the greater tuberosity of the humerus. At the time this X-ray was taken, the subdeltoid bursa was moderately distended. This was a case of exudative subdeltoid bursitis with a sub-bursal deposit, three weeks duration

swelling and fluctuation of the subdeltoid bursa, limited motion due to muscle spasm, sublaxations and tenderness over the lesser tuberosity of the humerus

Pain—The pain is very intense, spasmodic in character, aggravated by motion and pressure and usually is worse at night. It frequently radiates down to the outer and middle third of the humerus. Very frequently, the pain will radiate down to the hand and fingers and simulate a true neuritis. This is due to the implication of the articular branches of the circumflex nerve supplying the subdeltoid bursa in an associated inflammatory process. The involvement of this nerve prolongs the pain and disability in the great majority of cases

Limited Motion—Abduction and rotation are greatly restricted. The patient may be able to abduct the arm from the chest wall a few degrees, beyond which point an intense muscle spasm exists which prevents further abduction. As the inflammation subsides an increasing degree of abduction can be obtained. Forward flexion and extension is fairly free, even in the acute stage, the patient is able to swing the

arm forward and backward freely. As the condition becomes chronic and is untreated, a contracture of the humero-scapular and costo-humeral takes place. In these instances the arm is bound down tightly against the chest wall and the motion that is present, is due largely to scapular rotation. Stiffness or limited motion is most persistent and may last for weeks, months or even years. In some cases, restriction in joint range is so marked, that it resembles an ankylosis. If it were not for the X-ray, we might be tempted to consider it such, the picture in the cases of which we are writing, showing normal cartilage

Swelling—The subdeltoid bursa is distended, raising the entire deltoid muscle from the capsule of the joint and increasing the size and roundness of the shoulder to a marked degree. From a differential diagnostic standpoint, if it were fluid within the joint, the deltoid region would not bulge, because the strong reinforcing coraco-humeral band of the capsule does not yield. An increased amount of fluid in the shoulder joint causes the capsule to bulge posteriorly, or in the bicipital sheath, fluctuation being most readily demonstrated behind or below the spine of the scapula or over the biceps. In the latter, it resembles a sausage shape tumor over the outer side of the upper arm

FIG 2—Case 4—Six-weeks later. Note that the deposit is now about the size of a split pea. This patient received 17 diathermic treatments and wore an aviation splint for six weeks. Normal function was restored in two months after treatment was started

Subluxations—In a comparatively few instances, I have observed slight downward or subglenoid subluxations of the shoulder when a large effusion is present. This may be

FIG 3—Case 3 Shows a large calcific deposit practically filling the space between the acromion process and the humeral head and greater tuberosity. Shoulder disability of five months duration.

demonstrated by noting the apparent increase in the length of the upper extremity as it hangs in a dependent position. The space between the acromion and greater tuberosity is increased. I believe these subluxations are caused by the hydro-static pressure of the distended bursal sac upon the greater tuberosity of the humerus. These findings are always confirmed by the X-ray. One of the cases recently seen and submitted herein illustrates this point.

It must be borne in mind that the shoulder maintains its position mainly through muscular action. The ligaments are loose structures and do not, per se, offer sufficient tension to approximate the head of the humerus to the glenoid cavity. For this reason the shoulder joint is the most frequently dislocated. Subluxations, due to sub-deltoid bursitis, spontaneously recover when the effusion subsides.

Grating—I have heard a distinct grating sound when the humerus rotates underneath the acromion. This may be due to the presence of the calcific deposits which lie between these bones.

Atrophy—Deltoid atrophy is a conspicuous symptom in the chronic case. The normal rounded appearance of the shoulder is changed

now to a flattened contour. I believe these atrophic changes are due to two causes. First, lack of use, second, to degenerative changes in the circumflex or axillary nerve, which is implicated to a considerable extent in an inflammatory process.

X-Ray Examination—In a fairly large percentage of cases, dense shadows are observed in the space between the acromion process and the greater tuberosity of the humerus. These may be single or multiple, large or small and may be in intimate relation with the greater tuberosity. In the past, before we knew very much about this disease, these were thought to be fragments of bone from the tuberosity of the humerus, but we know now that they have no relation with this process. These deposits are never found in the bursal sac, but in the tendons or the bursal walls. The deposits may be semi-solid resembling tooth paste in color and consistency or they may be dry, gritty and dark brown in color. Very frequently, calcific deposits may be discovered by an X-ray examination taken for other reasons, when the patient was not cognizant of trouble in the shoulder. There might have been a history of traumatism which was so slight that the patient paid no attention to it. This emphasizes the point that the deposits of themselves may not be the cause of the painful symptoms of this disease, but it is the effusion

FIG. 4—Case 3 Two months later treated by diathermia alone. Note that only a small fragment remains. This patient obtained complete relief of pain and excellent shoulder function.

observed this disease most frequently in adults between the ages of 35 and 60

Symptoms—The cardinal symptoms of acute subdeltoid bursitis are pain in the shoulder,

FIG 1—Case 4 Shows a large calcific deposit capping the greater tuberosity of the humerus. At the time this X-ray was taken, the subdeltoid bursa was moderately distended. This was a case of exudative subdeltoid bursitis with a sub-bursal deposit, three weeks duration.

swelling and fluctuation of the subdeltoid bursa, limited motion due to muscle spasm, subluxations and tenderness over the lesser tuberosity of the humerus.

Pain—The pain is very intense, spasmodic in character, aggravated by motion and pressure and usually is worse at night. It frequently radiates down to the outer and middle third of the humerus. Very frequently, the pain will radiate down to the hand and fingers and simulate a true neuritis. This is due to the implication of the articular branches of the circumflex nerve supplying the subdeltoid bursa in an associated inflammatory process. The involvement of this nerve prolongs the pain and disability in the great majority of cases.

Limited Motion—Abduction and rotation are greatly restricted. The patient may be able to abduct the arm from the chest wall a few degrees, beyond which point an intense muscle spasm exists which prevents further abduction. As the inflammation subsides an increasing degree of abduction can be obtained. Forward flexion and extension is fairly free, even in the acute stage, the patient is able to swing the

arm forward and backward freely. As the condition becomes chronic and is untreated, a contracture of the humero-scapular and costo-humeral takes place. In these instances the arm is bound down tightly against the chest wall and the motion that is present, is due largely to scapular rotation. Stiffness or limited motion is most persistent and may last for weeks, months or even years. In some cases, restriction in joint range is so marked, that it resembles an ankylosis. If it were not for the X-ray, we might be tempted to consider it such, the picture in the cases of which we are writing, showing normal cartilage.

Swelling—The subdeltoid bursa is distended, raising the entire deltoid muscle from the capsule of the joint and increasing the size and roundness of the shoulder to a marked degree. From a differential diagnostic standpoint, if it were fluid within the joint, the deltoid region would not bulge, because the strong reinforcing coraco-humeral band of the capsule does not yield. An increased amount of fluid in the shoulder joint causes the capsule to bulge posteriorly, or in the bicipital sheath, fluctuation being most readily demonstrated behind or below the spine of the scapula or over the biceps. In the latter, it resembles a sausage shape tumor over the outer side of the upper arm.

FIG 2—Case 4—Six weeks later. Note that the deposit is now about the size of a split pea. This patient received 17 diathermic treatments and wore an aviation splint for six weeks. Normal function was restored in two months after treatment was started.

Diagnosis—The diagnosis rests upon the history of the onset and development, the location and radiation of the pain, the tests of shoulder mobility, the pathognomonic point of tenderness to pressure over the lesser tuberosity of the humerus and finally, the X-ray evidences of calcific deposits

Treatment—In a practical consideration of

branches of the axillary nerve supplies
Acute Subdeltoid Bursitis—The prime indication is to relieve the increased intra bursal tension and to relax the spinati tendons by putting the shoulder at rest in the abducted position, either in bed or by splints, for a period of a week, or ten days, depending upon the intensity of the symptoms When a large effu-

the therapy of subdeltoid bursitis, it would seem best to divide it, first, into the treatment of the primary attack or acute exacerbation of an ancient calcific subdeltoid bursitis, second the treatment of the chronic stage of the disease, characterized by increasing stiffness and pain in the shoulder, due to lime deposits, adhesions and implication of the articular

sion can be demonstrated, aspiration, under strict aseptic precautions is a measure of great value, relieving the painful symptoms of the disease expeditiously Sodium salicylate combined with sodium bicarb grains XX every two hours can be administered per os, during the acute stage, being remarkably analgesic in its effect This combination may be

within the bursa or adhesions which form between the walls which cause the disability I might state that these deposits are potential factors of harm, because, being foreign bodies,

FIG 5—Case 5 Shows a calcific deposit in relation with the greater tuberosity. Duration of disability, ten days. The bursal sac was distended, muscle spasm and pain intense.

the least strain or minor injury may initiate an exacerbation in the bursal sac.

General Symptoms—As a general rule, these patients do not have any temperature elevations or increase in pulse rate. Because of the intense and intractable pain, they are highly neurotic, their morale is undermined from the worry and sleepless nights. They are irritable, lose weight, become anemic and exhausted, in fact, present every evidence of pain and suffering.

PATHOLOGIC TYPES

(1) *Acute Exudative Subdeltoid Bursitis*

The essential lesion in this variety is an acute exudative inflammation of the subdeltoid and subacromial bursae. The bursal sacs are distended with a serous fluid, the increased tension giving rise to the symptoms indicated above. Calcific deposits, beneath the bursal floor, recent or ancient, are frequently associated findings. Spontaneous absorption of the exudate and of the calcific deposit may occur.

(2) *Subacute Adhesive Subdeltoid Bursitis*

Usually the secondary stage of an exudative bursitis. Progressive loss of function, persist-

ent pain, muscular atrophy and neuritis of the circumflex nerve are the leading symptoms. The synovial membrane is thickened and agglutinated by adhesions. Loculated collections of serum are frequently noted. Beneath the bursal floor, the findings are, calcareous, degeneration of the tendons and tendon sheaths of the infra and supra spinatus muscles, granulation tissue infiltrated with lime salts, cortical erosions of the greater tuberosity of the humerus may also be occasionally observed. Spontaneous recovery, in this type of the disease does not occur.

(3) *Chronic Periarthritis of the Shoulder*

Complete loss of shoulder mobility, persistent pain, atrophy of the muscles of the shoulder girdle, are the cardinal symptoms. The articular surfaces are intact and the lime deposits are absent. Contracture of the pectorals and scapulo-humeral muscles is present, due to a chronic fibro-myositis. The bursal walls are agglutinated by adhesions.

(4) *Calcific Tenosynovitis of the Supra and Infra Spinatus Without Symptoms*

Roentgenologists have noted the presence of calcific deposits in shoulders without symptoms. These lime deposits are usually found in the sheaths of the spinatus tendons. They are probably souvenirs of an ancient tenosynovitis, traumatic in origin. Calcific tenosynovitis is not an uncommon condition, in other tendons of the body. I have recently seen a case of calcific tenosynovitis of the achilles tendon.

FIG 6—Case 5 Three weeks later, treated by abduction, in bed for one week, diathermia for two weeks. Note deposit completely absorbed. Excellent function.

these movements should be performed slowly and thoroughly. While the arm is fully abducted, the elbow is forced backward. During all these movements, the scapula is fixed. It should now be released and allowed to partici-

encouraged to take mild exercises. When healing is complete, a course of baking and massage is given.

Two of my earlier cases in the series indicated above were operated upon. Probably as good results could have been obtained had they been treated conservatively.

In the first case, upon incising the bursal cavity, a small collection of serum was evacuated. Beneath the bursal floor, a soft putty-like mass, the size of an almond, was found lying upon the tendon of the supraspinatus muscles. No adhesions were found. This patient recovered completely in four weeks.

The second case was one of simple exudative bursitis of five weeks duration. The bursal cavity was incised and drained, an abduction cast applied, which he wore for two weeks. This patient obtained excellent function in four weeks.

Comment—In the treatment of subdeltoid bursitis, experience has shown that conservative measures should supersede surgical procedures. Spontaneous recovery occurs even in the calcific variety of the affection. The measure which seems to be most beneficial and gives gratifying results is rest of the shoulder in the abducted position combined with diathermia. The latter is the remedy par excellence.

Eight of the twelve cases, suffering from this affection, responded most remarkably to

FIG 9—Case 10. Shows a large calcific deposit filling the space between the acromion and the humeral tuberosity and head. Intense pain and spasm. The bursal sac showed a moderate effusion. Duration of disability two weeks.

pate in these motions. A day or two later, the patient is encouraged to actively exercise the shoulder and in the course of time, function gradually returns.

Operations—Occasionally cases treated along the lines referred to above do not respond. The stiffness and pain persist in spite of everything that has been done. The calcific deposit may have entirely disappeared but adhesions between and hypertrophy of the bursal walls remain, which not only interfere with function but produce other symptoms incident to this disease. In these cases, surgical intervention is found necessary. The bursa may be excised or adhesions divided, leaving the sac intact.

If found extensively infiltrated, the walls matted together by dense adhesions, complete excision of the sac is indicated. Lime deposits and granulation tissue beneath the bursal floor are thoroughly cleaned out. The wound is closed in layers without drainage. A bandage is then applied to the shoulder with a thick axillary pad in the axilla to secure slight abduction. At the end of a week, the patient is

FIG 10—Case 10. Two weeks later, treated daily by diathermia. Only a small fragment in relation to the greater tuberosity is now visible. Function returning and pain only on external rotation.

continued for a week or ten days. Tinnitus and nausea may arise, indicating an intolerance toward these drugs. Under these circumstances, the intervals of administration may be lengthened.

FIG. 7—Case 12. Shows a large calcific deposit and sub-glenoid subluxation of the humerus. Duration of disability three months. Muscle spasm and pain intense, moderate effusion in the bursal sac.

Usually, at the end of three weeks, the ordinary case of subdeltoid bursitis with effusion, will have recovered.

While there is no evidence to indicate that focal infections have a relation to this disease, it is wise to eradicate any existent foci (diseased tonsils or bad teeth and the like) because the inflamed shoulder may become a locus minoris resistentia to any infectious process.

If stiffness and pain persist and lime deposits be present, diathermia should be employed. This is, without a doubt, the remedy par excellence in the calcific form of the disease, producing a rapid absorption of the deposits. The marvelous results often seen after two weeks of daily treatment with diathermia, is due to the heat generated within the deeper tissue by the passage of the high frequency current. The improved arterial, venous and lymphatic circulation enhances absorption of effete pathologic products. Inflammatory adhesions, characteristic of so many of these cases, are not so prone to form, if diathermia is instituted early enough.

Calcific Subdeltoid Bursitis Without Sym-

toms—It is a well-known fact that there are numbers of patients with deposits, in either one or both shoulders, which do not give rise to much pain or disability. The question arises whether such cases should be treated. As a prophylactic measure, I believe that these deposits should be removed, preferably with diathermia. As foreign bodies, they may irritate and set up, at any time, an acute inflammation in the bursa, producing the train of symptoms described above.

Chronic Subdeltoid Bursitis—The great majority of cases can be relieved of pain and function restored by persistency in physiotherapy (diathermia, massage and passive manipulations). A small percentage of cases require manipulations under an anesthetic or open operation either excision of the bursa or division of adhesions.

Adhesions, resulting from inflammation of the periarticular structures of the shoulder, may be broken down under ether anesthesia. Complete muscular relaxation must be obtained. The arm is first abducted, care being taken not to strain the joint by over-abduction. An assistant fixes the scapula and fist in the axilla, puts pressure upon the head of the humerus to prevent dislocation. With the arm lying at the side of the chest and afterwards in the position of abduction, the humerus should be rotated inward and outward,

FIG. 8—Case 12. Two weeks later. The deposit has been considerably absorbed. Note the cortical erosion of the greater tuberosity. The head of the humerus is now in normal relation with the glenoid cavity. The patient did not respond to treatment and an operation was advised but refused.

of toxic disturbance trying first this medicinal remedy and that with a steady downward trend. Before this stage is reached the patient should be put to bed for a few days and visitors denied.

Insure sufficient sleep by the administration of veronal or luminol, in fact luminol may be given in quarter-grain doses throughout the waking hours. The patient should not be questioned as to her choice of food but it should be brought to her served in an appetizing manner and she should be urged to partake of it. If plain water is not tolerated weak tea or preferably carbonated water such as the alkaline Kalak or ginger ale which has the advantage of containing sugar should be administered. As improvement is noted her diet may be increased gradually but the resumption of normal activities must be gradual.

Should the condition remain stationary or grow worse as shown by the inability to retain little or any food accompanied by loss of weight and signs of dehydration the patient should be hospitalized and all visitors excluded. Here again I would urge that this be done while treatment will be availing to effect improvement. I have seen many cases in consultation where the physician in charge thought the uterus should be promptly emptied and which had been treated at home in a more or less casual manner and none of the measures tried which today we recognize as of benefit in the treatment of this condition.

The services of day and night nurses are indispensable, the room should have an abundance of fresh air and be as free from noise and disagreeable odors as possible. The treatment must to a certain extent be individualized, but can be summarized for the sake of convenience as follows:

- daily examinations of urine including acetone and diacetic acid determinations
- nothing by mouth for 24 hours
- 500 cc. 10% glucose intravenously to be given very slowly (200 to 250 cc. per hour)
- to be repeated in 12 hours if no improvement is noted
- In addition if dehydration is marked 1000 cc. salt solution intravenously
- Sod bromide grs XL in eight ounces of 5% sodium bicarbonate solution per rectum every 4 hours till patient is quite drowsy. This may be alternated with—5% glucose solution 250 cc per rectum

In some cases the drip method is well tolerated but most patients will retain both glucose and bromide solutions better in small amounts given at once than by the continuous flow.

Titus of Pittsburgh has focused attention upon the intensive use of glucose intravenously.

The writer used glucose intravenously several years ago with rather indifferent result due now I am sure to two reasons *first*, reactions (chill

etc.) which followed its use caused either by the use of impure glucose or by too rapid administration, *second*, to insufficient amounts, since the C P product has been used and its rapidity of administration reduced. I have seen no disagreeable reactions and the improvement has been marked.

Whether the vomiting is the cause of the acidosis or the result (and they are probably both due to the same factor) we need not be particularly concerned so long as results follow treatment.

I have seen striking results follow the relief of dehydration by giving a litre of salt solution subcutaneously or preferably intravenously. Harding and Van Wyck of Toronto lay stress upon the value of fluids and gauge their results by the diuresis resulting, claiming that fluids alone produce results and that glucose is not necessary.

I have seen one case which would seem to argue for this theory. This woman was the nearest to death of any case I have seen recover. She was seen in consultation on a Sunday afternoon, her uterus had been emptied in the Friday previous after five weeks' of vomiting, she grew worse instead of better between Friday and Sunday and I did not believe she would live till midnight, she was sent to the hospital and I quote from the interne's notes:

"Semi comatose young woman, vomiting—markedly dehydrated and very poor color, eyes sunken and face drawn—appears extremely weak, radial pulse not palpable. Systolic B P 70, heart 130. Has apparently lost much weight urine albumin four plus

acetone " "

diacetic acid " "

blood N P N 66 " "

uric acid 85

She was given 500 cc of 3% glucose (15 gms) intravenously and eight ounces 5% glucose per rectum every 3 hours, later 500 cc salt solution intravenously. The next day she had a perceptible radial pulse and her mind began to clear. She retained some ginger ale. After two unsuccessful attempts, a duodenal tube was kept down on the second day and quantities of glucose solution put down, she continued to improve and was discharged in 10 days. That this woman lived, I believe, was due to the glucose solution partially but also to the quantities of fluids given, for the dosage of glucose was small compared to what would have been given her today.

Insulin used in conjunction with glucose intravenously is of value in the case where liver damage is so advanced that complete oxidation of the carbohydrate intake is impossible. It is given with the glucose and the patient should not be left during the administration, in most cases its addition to the glucose is unnecessary. Fluids by the mouth preferably carbonated beverages

diathermia The duration of the disease ranged between ten days and six months. In practically every one, after daily treatment, the X-ray showed, at the end of a month, absorption.

Another remarkable feature that should be emphasized is the effect of diathermia upon

function. The shoulder movements became more free and pain was greatly lessened even after a few treatments.

Surgical Treatment—Excision or division of the adhesions should be reserved for the sub-acute or chronic case which has not responded to the above conservative measures.

THE MANAGEMENT OF VOMITING OF PREGNANCY*

By JAMES K. QUIGLEY, M.D., F.A.C.S., ROCHESTER, N. Y.

ABOUT forty per cent of pregnant women are entirely free of nausea and vomiting, of the remaining, one-half, or thirty per cent, have little more than the morning attack, the balance approximately another thirty per cent suffer more or less all of the day and often into the night from nausea and retain little or no food—this number includes the class known as pernicious vomiting, uncontrollable vomiting or hyperemesis gravidarum. This is no inconsiderable number, almost one-third of our patients and demands the best that we can offer for its relief.

Pregnancy imposes a burden on the metabolism which in half the cases is compensated for and no symptoms result, the remaining fifty per cent suffer from more or less annoying symptoms such as pruritus, localized or general, muscular cramps, headaches, salivation, vertigo, fainting attacks and nausea and vomiting, these in my opinion are all manifestations of toxemia of varying intensity, while there is some basis for the usual text book classification of vomiting viz, reflex, neurotic, toxic and essential or that form in which some pre-existing condition is made worse by pregnancy such as gastric ulcer, cholelithiasis or tubercular peritonitis. Nevertheless I believe all cases are basically toxic.

What this toxic agent is or where elaborated we have no knowledge, but its activity is dependent upon the life of the foetus, for on death of the foetus even though the product of conception be retained, nausea and vomiting cease unless the liver has become so much involved that carbohydrate metabolism is impossible.

That neuroses play a large part in the etiology of some cases is undeniable, but this I think is secondary—and from the standpoint of therapeutics it is better to consider all cases essentially toxic some of which demand special consideration and treatment, and not to lose sight of the fact that any of these cases may pass on to the stage of hyperemesis and consequent liver damage. Examples of purely reflex vomiting are so rare as to be considered negligible.

Vomiting of pregnancy is often worse in each succeeding pregnancy. I have seen a few exam-

ples recently exceptions to the rule, one a patient so toxic as to require a therapeutic abortion a few years ago who in her present pregnancy has had only a little nausea and vomiting, and another also very ill during two previous pregnancies had no nausea and no vomiting in her present one.

Management of mild cases of vomiting is many times discouraging both to patient and physician but with co-operation from the former and with more attention to detail by the latter much can be done to make these patients more comfortable, and what is more important prevent them from growing worse.

Impress upon the patient that her condition in the majority of cases is limited, treated or untreated, and does not persist throughout pregnancy—and that if she follows instructions improvement will follow though she probably will not be entirely free of vomiting before the twelfth week that she should have diversion, fresh air, moderate exercise out of doors with sufficient elimination by the bowels. She should be given food in bed before arising, toast or crackers and black coffee, or if it is found that vomiting is inevitable and contains bile and mucus a copious draught of hot water containing bicarbonate of soda will be almost as efficacious as tube lavage, so that nourishment taken later has a better chance of remaining.

As nausea and vomiting often occur when the stomach is empty a light lunch should be taken midway between meals, in fact five to six lunches are better tolerated than three large meals, solid food is better than liquids and should be chiefly of the carbohydrates. If she expresses a desire however for any particular food it should be tried. The appetite is often capricious and it is well known that women will sometimes retain strange things, for instance, fried ham has been retained where champagne was rejected. Although uncomfortable for a time these patients do not get on so badly for they are enabled to retain nourishment during a part of the day sufficient to prevent loss of weight or energy. When the case passes over to the class of moderate severity I believe time to employ measures sufficiently intensive to prevent hyperemesis, in other words instead of waiting for severe signs

* Read at the Annual Meeting of the Medical Society of the State of New York, at New York March 30 1926

irradiation should be employed in every case of tuberculous peritonitis before resorting to surgical interference

This form of treatment likewise is of value in connection with tuberculosis of the bones, joints and glands. It cannot be expected that it will entirely replace surgical measures. For example, if there is pus, it will have to be evacuated, and, if there is a sequestrum, it will have to be removed. In my experience, the degree of success in these forms of tuberculosis is not as great as in tuberculosis of the peritoneum. I have had but little experience with the treatment of pulmonary tuberculosis by this means. Those who have had a large experience are cautious in expressing an opinion as to the indications for ultra-violet irradiation in this type of the disease. It would seem important in cases of this kind that the irradiation should not be intense, but should be carried out less vigorously and for a longer period. Where heliotherapy is employed, care should be observed that the patient does not become overheated and, therefore, the treatment had best be carried out in the morning before the sun has reached its meridian.

Many physicians have reported a general tonic effect from the use of irradiation from artificial sources. The general condition of the child is improved, the appetite stimulated, sleep is sounder, and the vigor is more marked. There is no doubt that one or more of these favorable results frequently follow a series of irradiations. In other instances, however, we have failed to obtain any of the desired effects. The appetite remains unaffected, sleep is still fitful, and there is no gain in weight. The puzzling aspect of this experience is that we cannot distinguish by any clinical or laboratory test between those children who will be benefited and others who fail to be improved by this treatment. It is quite true that in general brunettes seem to be improved more than blondes. But although this rule holds as a general principle, it must be accepted with reservations. Probably the marked difference in our results is due not so much to a difference in the constitution of the individual child, as to a distinction in the nature of the symptoms which we are attempting to alleviate.

Ultra-violet therapy is being employed largely to prevent the development of "colds", or so-called "grippe" infections. It is, I believe, the general experience that some children are subject to frequent "colds" and catarrhal infections throughout the winter, a susceptibility which bears no relationship to their general health and vigor. In order to ascertain whether this highly undesirable condition, which often leads to more serious sequelæ, could be abetted by irradiation, a test was carried out in the Home for Hebrew Infants

to ascertain whether a group of young children which were treated regularly by the mercury vapor lamp developed "grippe" infections less frequently than a similar group of children which were not so treated. The children, about 50 in all, were 6 months to 3 years of age and were in 2 wards, one-half the number were irradiated every other day for a period of over 3 months, whereas the others received no treatment whatsoever. This study will be reported in detail at another time. It may be stated, however, that the results were thoroughly convincing that this form of ultra-violet irradiation did not decrease the incidence of these infections. It was found also that this therapy did not prevent the occurrence of whooping cough or of chicken-pox. Some children manifested these diseases in spite of the fact that they had undergone treatment throughout the incubation period, and were still being treated at the time these infectious diseases developed.

Ultra-violet therapy is being used extensively for skin diseases. In my experience, it has been of decided value in preventing and in curing multiple furunculosis. In a case of this kind, the furuncles should be incised and the pus evacuated as it develops, and irradiation carried out in the usual way. The success of heliotherapy has been very marked in some instances. This success may be due in part to the reduction of excessive perspiration, which so frequently is associated with furunculosis. In the treatment of eczema, the results have been unsatisfactory—occasionally good but often nil.

The question is asked frequently as to what type of lamp is most effective in ultra-violet therapy. In this country two types are mainly employed—the mercury vapor and the carbon arc lamps. From a practical point of view, each of these has its peculiar advantages. The mercury vapor lamp, although more expensive, costs less to maintain. Its great advantage, however, is that it can be adjusted to the ordinary light socket and, therefore, can be readily employed in any household. Its disadvantage is that owing to the shortness of the waves of ultra-violet light which it generates, it tends to produce superficial burns, unless its intensity is carefully controlled. The carbon arc light uses at least 15 amperes, and thus cannot be adjusted to the ordinary electric light socket, and is more expensive to maintain. Furthermore, the carbons have to be replaced after they have been burned for some hours, and a disagreeable ash is produced from the burning of the carbons. The chief advantage of this type of lamp is that it does not cause burns and can be manipulated by an untrained or unskilled person. It may be added

like champagne or ginger ale should be given after 24 to 36 hours in teaspoonful amounts, later dry toast or crackers may be tried, still later cooked cereals and dry toast may be added.

While this plan of treatment will clear up most cases of hyperemesis and while fewer cases will require therapeutic abortion than did five years ago nevertheless in order to save life it may rarely be necessary to empty the uterus. What shall be the indications for this procedure? Unfortunately we have no sure test of liver function and are forced to depend upon a clinical summary, rapid loss of weight, vomiting of blood, persistently rapid pulse, lessening of the amount of urine, urine containing bile pigment, we should of course never wait for all of these symptoms and in the last analysis it becomes a question of individual judgment or rather the judgment of two of three. The case that shows no improvement or grows worse after twenty-four hours of treatment as outlined above should be aborted with as little shock as possible under nitrous oxide anesthesia.

A word of caution, cessation of vomiting and retention of food is not always per se, an indication that all is well.

Two years ago a woman was seen outside and later admitted to the hospital, had vomited five weeks but this day had retained solid food and had not vomited. Her pulse was 90, there was only a trace of acetone and diacetic acid, she was given fluid subcutaneously and glucose per rectum, on the second day she received glucose intravenously. Because of a rising pulse she was aborted on the third day and given glucose intravenously three times. She died and on autopsy a typical liver of acute yellow atrophy was found.

CONCLUSIONS

1 More intensive treatment of vomiting of moderate severity will prevent many cases from becoming pernicious.

2 Intensive treatment of the pernicious type with fluids and glucose solution preferably intravenously will prevent many therapeutic abortions.

THE USE AND MISUSE OF ULTRA-VIOLET THERAPY*

By ALFRED F HESS, M D, NEW YORK, N Y

THERE can be no doubt that we are on the wave—whether on the crest is still uncertain—of a remarkable manifestation of interest in irradiation. This form of therapy is being employed not only by physicians and surgeons in almost every branch of medical practice, but is being made use of by the layman as well. Under the circumstances, it would seem opportune to consider what experience has taught us in relation to the use of this new therapeutic agent.

It is a commonplace to state that ultra-violet therapy, whether carried out in the form of heliotherapy or by means of radiations from artificial sources, is a specific in the cure or prevention of rickets and tetany. All reports have been in agreement in this regard, and there have been no dissenting voices. The degree of specificity in relation to these two allied disorders is exceptional, for whereas most specifics fail from time to time, for example quinine in malaria or mercury in syphilis, ultra-violet irradiation seems to be well nigh an absolute specific. In cases where cod liver oil—another specific in rickets and tetany—fails in its curative properties, ultra-violet irradiation will frequently prove effective. Even in relation to the rickets of the premature baby, who is peculiarly susceptible to this disorder, this form of light therapy has been found to

be of unequalled value. A similar preventive or curative effect can be brought about in an indirect way. As I showed about two years ago, it is possible to convert inert foods into active antirachitic substances by means of exposing them to ultra-violet irradiations. For example, a vegetable oil, such as cotton seed oil, can be metamorphosed in this way. Vegetables, such as spinach or carrots, have been shown to acquire protective potency by this procedure and to have developed curative properties for rachitic infants. The same is true for dried milk, which in this connection seems to offer the most promising outlook for therapeutic purposes.

In addition to its use in rickets and tetany, there can be no doubt but that ultra-violet irradiation is of great value in tuberculosis. I have seen infants and young children who were suffering from progressive tuberculosis of the peritoneum cured by means of heliotherapy or the radiations from a mercury vapor or carbon arc lamp. When the radiotherapy was begun, these children were poorly nourished and showed the typical symptoms of this form of tuberculosis—abdominal masses associated with fluid in the peritoneal cavity. As the result of a few months' treatment, the picture was entirely changed. Their general condition had greatly improved, they had gained in weight and the local signs had either disappeared or markedly diminished. Ultra-violet

* Read at the Annual Meeting of the Medical Society of the State of New York at New York, March 31, 1926.

of the point of view which was held some 25 years ago when the Roentgen rays were first introduced into clinical medicine. The comparison is probably somewhat exaggerated, but it is suggested by the uncritical use of these radiations at the present time. Until we learn more of the physiological action of these short rays, great care should be exercised both in regard to the selection of cases and in the dosage in which they are employed. In this connection, a word may be in place in regard to carelessness in protecting the eyes in the course of carrying out this therapy. As is well

known, ultra-violet rays are irritating to the eyes and produce a painful conjunctivitis. In order to avoid this irritation, the operators are strongly advised to wear colored glasses. It has been my experience that many physicians and technicians fail to apply these glasses. In view of the fact that cataract is of such frequent occurrence in India, and that this high incidence has been ascribed by many to the marked intensity of the sun in that country, it is possible that years of frequent exposure to the radiation from these lamps might lead to similar changes in the lens.

FURTHER ADVANCEMENT IN THE TECHNIQUE AND INTERPRETATION OF CHOLECYSTOGRAPHY BY THE ORAL METHOD*

By WILLIAM H STEWART, M D, and ERIC J RYAN, M D, NEW YORK, N Y

SINCE Drs Graham, Cole and Copher have shown us how to render the bile opaque to the X-ray and thus make it possible to visualize the gall bladder we have been able to materially increase the percentage of our correct roentgenographic findings in cholelithiasis and pathology of the gall bladder.

The intravenous injection of tetrabrom and tetraiodo phenolphthalein as recommended by the originators of the method was so disastrous to the patient that we were forced to discontinue this method of administration. It became evident at once that if there was any hope of visualization of the gall bladder becoming as valuable as the visualization of the gastro-intestinal tract the method must be simplified so that it would be safe and could be used as a *routine office procedure* not requiring the hospitalization of the patient. Investigations were then made with the oral administration of the dye.

It soon became apparent that to obtain the best results the dye must not come in contact with the acid secretion of the stomach, but must pass on unchanged into the intestinal tract where absorption could take place. What we needed to accomplish this was a safe and reliable coating to pills or capsules containing the dye which would hold them intact in the stomach and allow them to be broken up in the intestinal tract. Up to September, 1925, we used tetraiodophenolphthalein in freshly made five grain keratine coated pills. They gave very satisfactory results, as the work was perfected, however, the demand for these pills became so great that the X-ray department assumed the appearance of a pill-making factory. About this time it became evident that the iodine salt was a very unstable drug, light and air rapidly deteriorating it to such an extent

that its value in rendering the bile opaque was markedly lessened. Some of the manufacturers of the dye were then persuaded to supply it in sealed, colored ampules, a single dose in each. This has overcome the deteriorating question. We then ceased the pill-making job and placed the fresh drug from the ampules into plain gelatine capsules which were dipped into a solution of keratine, this sealed them airtight and covered them with a coating which would prevent them from being broken up in the stomach. They are made up fresh for each case. In a great measure this has overcome any unreliability to the X-ray findings following the oral administration of the dye. In fact, we now have sufficient confidence in the method to use it routinely in our office, it is simple and efficient and can be carried on much the same as investigations of the gastro-intestinal tract with the barium meal.

It has recently been stated by a number of our roentgenological friends throughout the country that there is much more reaction following the oral than the intravenous administration of tetraiodo. This has not at all been our experience, in fact, of late, we do not have any reaction, unless one classifies as such, a slight nausea, one or two loose movements or an occasional vomiting attack. When this does occur it in no way incapacitates the patient. Without exception they appear at the office the morning following the administration of the dye and are strong enough to undergo the examination without breakfast and continue their fast until lunch time, about eighteen hours in all with no inconvenience.

There has been considerable controversy as to the relative value of the intravenous when compared with the oral method of applying the test. We do not admit that the oral method, properly carried out is less reliable than the intravenous. In fact, we particularly take ex-

* Read at the Annual Meeting of the Medical Society of the State of New York, at New York, March 31 1926

that the spectrum of its radiations approaches more nearly that of the sun

We do not know the physiological effect of the ultra-violet rays - That it leads to local and systematic changes is evident. Various constitutional alterations have been described, some claiming that the metabolic rate is increased and others that it remains unaltered. Pigmentation of the skin is brought about by the rays from these artificial sources. It is similar, but by no means the same, as the pigmentation which develops as the result of exposure to the rays of the sun. It is of a more brown and less ruddy shade. The skin becomes smoother and of a better texture, it is more elastic and seems to be found down more firmly on the underlying connective tissue. The muscles also become firmer and fuller. These changes in the skin and subadjacent tissues formed one of the most marked and distinctive points of differentiation between the group of children which had been irradiated regularly throughout the winter, and the group which had received no such treatment.

Our chief difficulty in carrying out this form of therapy lies in the fact that we have no adequate method of measuring the dosage. Many gauges have been suggested for this purpose but none is satisfactory. At the present time we are forced to follow a purely empirical method. In the case of the mercury vapor lamp, our guide as to the intensity of treatment—duration of irradiation and distance of lamp—is the avoidance of marked erythema or superficial burns. As a matter of fact, neither erythema nor pigmentation is a correct gauge of therapeutic dosage. By employing small and frequent applications of these irradiations, I have been able to cure cases of rickets without bringing about the slightest degree of erythema or pigmentation. It is not difficult, however, to judge whether we are giving a sufficient degree of irradiation. This fact can readily be ascertained by observing the course of the disease, for example, in the case of rickets by noting the improvement of the clinical signs, the calcification of the epiphyses as seen by the Roentgen rays and the increase in the percentage of inorganic phosphorus in the blood. But how are we to know whether the intensity is unnecessarily great and, furthermore, is it of no consequence whether we employ too great an intensity?

It has been my experience in general—observations which were borne out in the study carried out this winter—that children frequently do well following the initial treatments but that this phase is succeeded by a static period. Sometimes improvement is noted after 3 or 4 treatments, and then ceases, more often, this second phase comes about after 8 or 10 treatments. Our procedure in treatment, which is

entirely empirical, is as follows. Irradiation is carried out every other day for a period of a month to six weeks. Then an interval of 2 to 4 weeks is allowed and the course of treatment is repeated, if this is found to be necessary. The lamp is placed at a distance of 3 feet from the body and exposures are made for 2 minutes on the front of the body and 2 minutes on the back. This duration is increased 1 minute on the front and back at each succeeding exposure. These rules are merely of general application and must be modified according to the individual case. As is well known, blondes are more sensitive to these radiations and are apt to burn as the result of their application. We must, therefore, be especially on our guard in treating fair individuals. The same is true in regard to markedly atrophic infants.

The initial phase of marked improvement which has been noted clinically can be substantiated by observations in the laboratory. Recent investigations would seem to show that the effect of irradiation in rickets is due largely to an activation of the cholesterol in the epidermis. It has been demonstrated in a series of papers that cholesterol, which is present in every animal cell, although inert in relation to rickets, becomes a specific antirachitic substance after exposure to ultra-violet radiations.

Now the epidermis is particularly rich in cholesterol, and it is probable that the effect of these radiations, which we should remember have very slight penetrating power, is to convert this inert epidermal cholesterol into an active antirachitic substance. Laboratory experiments seem to indicate that this cholesterol is not activated in direct ratio to its exposure to ultra-violet radiations, but that it undergoes a sudden and somewhat precipitous activation at the outset of irradiation. In other words, these laboratory experiments seem to bear out and fortify the clinical experience of an exceptional activation following initial treatment with ultra-violet light. The studies of the laboratory likewise warn us of the possible dangers of over-irradiation. If we continue the irradiation of cholesterol for too long a period, let us say for 3 or 4 hours or more, it is found that although it had been activated, it has been converted once more into an inert substance, and that when fed to animals, it is no longer able to protect against rickets. Furthermore, it cannot be reconverted into an active chemical material. Although these laboratory investigations should not be transferred bodily into the clinic, they lend weight to the dangers of over-irradiation and to a possible negation of our results by exposures which are unduly prolonged.

We are still in the stage where many look upon ultra-violet light as an agent which can do much good but no harm. It reminds one

of the point of view which was held some 25 years ago when the Roentgen rays were first introduced into clinical medicine. The comparison is probably somewhat exaggerated, but it is suggested by the uncritical use of these radiations at the present time. Until we learn more of the physiological action of these short rays, great care should be exercised both in regard to the selection of cases and in the dosage in which they are employed. In this connection, a word may be in place in regard to carelessness in protecting the eyes in the course of carrying out this therapy. As is well

known, ultra-violet rays are irritating to the eyes and produce a painful conjunctivitis. In order to avoid this irritation, the operators are strongly advised to wear colored glasses. It has been my experience that many physicians and technicians fail to apply these glasses. In view of the fact that cataract is of such frequent occurrence in India, and that this high incidence has been ascribed by many to the marked intensity of the sun in that country, it is possible that years of frequent exposure to the radiation from these lamps might lead to similar changes in the lens.

FURTHER ADVANCEMENT IN THE TECHNIQUE AND INTERPRETATION OF CHOLECYSTOGRAPHY BY THE ORAL METHOD*

By WILLIAM H STEWART, M.D., and ERIC J RYAN, M.D., NEW YORK, N. Y.

SINCE Drs. Graham, Cole and Copher have shown us how to render the bile opaque to the X-ray and thus make it possible to visualize the gall bladder we have been able to materially increase the percentage of our correct roentgenographic findings in cholelithiasis and pathology of the gall bladder.

The intravenous injection of tetrabrom and tetraiodo phenolphthalein as recommended by the originators of the method was so disastrous to the patient that we were forced to discontinue this method of administration. It became evident at once that if there was any hope of visualization of the gall bladder becoming as valuable as the visualization of the gastro-intestinal tract the method must be simplified so that it would be safe and could be used as a *routine office procedure* not requiring the hospitalization of the patient. Investigations were then made with the oral administration of the dye.

It soon became apparent that to obtain the best results the dye must not come in contact with the acid secretion of the stomach, but must pass on unchanged into the intestinal tract where absorption could take place. What we needed to accomplish this was a safe and reliable coating to pills or capsules containing the dye which would hold them intact in the stomach and allow them to be broken up in the intestinal tract. Up to September, 1925, we used tetraiodophenolphthalein in freshly made five grain keratine coated pills. They gave very satisfactory results, as the work was perfected, however, the demand for these pills became so great that the X-ray department assumed the appearance of a pill-making factory. About this time it became evident that the iodine salt was a very unstable drug, light and air rapidly deteriorating it to such an extent

that its value in rendering the bile opaque was markedly lessened. Some of the manufacturers of the dye were then persuaded to supply it in sealed, colored ampules, a single dose in each. This has overcome the deteriorating question. We then ceased the pill-making job and placed the fresh drug from the ampules into plain gelatine capsules which were dipped into a solution of keratine, thus sealed them airtight and covered them with a coating which would prevent them from being broken up in the stomach. They are made up fresh for each case. In a great measure this has overcome any unreliability to the X-ray findings following the oral administration of the dye. In fact, we now have sufficient confidence in the method to use it routinely in our office, it is simple and efficient and can be carried on much the same as investigations of the gastro-intestinal tract with the barium meal.

It has recently been stated by a number of our roentgenological friends throughout the country that there is much more reaction following the oral than the intravenous administration of tetraiodo. This has not at all been our experience, in fact, of late, we do not have any reaction, unless one classifies as such, a slight nausea, one or two loose movements or an occasional vomiting attack. When this does occur it in no way incapacitates the patient. Without exception they appear at the office the morning following the administration of the dye and are strong enough to undergo the examination without breakfast and continue their fast until lunch time, about eighteen hours in all with no inconvenience.

There has been considerable controversy as to the relative value of the intravenous when compared with the oral method of applying the test. We do not admit that the oral method, properly carried out is less reliable than the intravenous. In fact, we particularly take ex-

* Read at the Annual Meeting of the Medical Society of the State of New York, at New York, March 31, 1926.

ception to the stereotyped assertion that the oral method should be checked with the intravenous

It is well to state that this work is not simple, it tries the skill of the roentgenologist to the utmost and necessitates the use of every known X-ray "stunt" in the making of a gall bladder examination, particularly does it require an intelligent patient who can and will suspend respiration during the making of the films. Reassurance on the part of the doctor and confidence on the part of the patient are absolutely essential before there can be any hope of success. Other things being favorable, the use of a gas tube and compression on a Potter Bucky Diaphragm will give the best results.

In making a roentgenographic examination of the gall bladder by the oral method the following technique must be accurately followed. The gastrointestinal tract should be thoroughly cleansed. This is best accomplished by a mild cathartic administered the night before the preliminary examination followed by a simple enema in the morning. This preliminary, or examination of the gall bladder before the administration of the dye, is best made in the afternoon. At 6 30 P. M., the following meal is advised. A thick soup, creamed chicken, baked potato if desired, bread and butter and a glass of milk. Commencing at 9 30 P. M. two five-grain capsules of the tetraiodo prepared as recommended are given every fifteen minutes with a small glass of water until 40 grains have been taken, which is the average dose for an individual weighing 150 pounds. The patient reports at the office the following morning at 9 30 A. M., twelve hours after the administration of the dye, "no breakfast being the rule." Four hours later, at 1 30 P. M., the examination is repeated. Regular lunch is then allowed followed by a reexamination one hour later. The patient reports the next morning for a final observation.

At least three roentgenograms should be made at each observation. It is well to develop one of these to be sure that the position and exposure is correct.

It is important to make a preliminary examination before the test, for the findings may be such as to make a diagnosis possible without the use of the dye.

The fatty meal is given to empty the gall bladder so that it will be in a receptive condition by the time the bile becomes opaque. The starvation from dinner to lunch the following day is essential in order to allow the gall bladder to fill and the bile reach its greatest concentration.

In normal cases the shadow should appear 12 hours after the dye is given, it should slightly diminished in size and become more in-

tense four hours later, as soon as food is given it should further diminish in size and detail or completely disappear. The following morning, thirty-six hours after the tetraiodo there should be no shadow of the gall bladder.

The technique having been developed to such an extent that it *can absolutely be relied upon*, it is obvious that our attention must be centered on the interpretation. It is now apparent that gall bladder lesions are recognized by both direct and indirect evidence. The most important of the *direct* signs is the actual visualization of non-opaque gall stones, these stones are recognized as circular negative shadows surrounded by the opaque bile. Some stones are not entirely non-opaque, the quantity of calcium salts, however, is so small that the detail without the dye is unsatisfactory. With the dye the roughened surfaces absorb sufficient of the opaque bile to accentuate the shadows so that they are readily recognized. Mottling of the gall bladder indicates small stones. One must be *extremely* careful in this interpretation, however, for gas in the duodenum often assumes small circular shadows similar to non-opaque stones. The danger of mis-interpretation is much greater when the duodenal shadows overlap those of the gall bladder.

Even with the aid of the test all gall stones cannot be visualized. It has happened that a calcium stone shown with the ordinary method of examination has completely disappeared by being overshadowed with the opaque bile. In the study of many series of cholecystograms we note that not unfrequently a small non-opaque gall stone will become visible as the gall bladder empties. Distention, while necessary in studying the function, often completely obliterates shadows within the lumen of the gall bladder, thus demonstrating the necessity of examinations both before and after the test as well as during the filling and emptying of the gall bladder with the opaque bile.

In a number of cases where the disturbance of function or deformity indicated a chronic cholecystitis, the surgeon at operation not only found a thickened wall gall bladder but stones as well. Here the shadow of the opaque bile in addition to that cast by the thickened wall of the gall bladder completely overshadowed the gall stones. In other cases the gall bladder is packed with non-opaque stones and as no dye impregnated bile can enter, the stones will not be recognized although the pathology will.

The second direct sign is deformity of outline. This may be due to a number of causes, the most common being adhesions. These adhesions may be of gall bladder or omental origin. When they are caused by cholecystitis the shadow is more apt to be deformed and the edges are likely to be roughened and

irregular, when caused by omental adhesions the *deformity* is present but as a rule the edges are clear cut and the entire outline of the gall bladder quite distinct. It has been noted that a deformed gall bladder shows best when partially empty. We have had numerous cases in our series which confirmed this statement. Adhesions of peri-cholecystitic origin may involve the duodenum, liver or colon without producing deformity. They can be recognized by malposition and fixation.

Probably much of the future development in cholecystography will be the early recognition of deformities to the gall bladder caused by pathology. It is often difficult to differentiate a deformed gall bladder due to adhesions and one due to pressure or to an anomaly.

One must bear in mind that one of the most important values of the Graham Test is in the detection of disturbance of function of the gall bladder. Up to the present time this disturbance has been recognized by four different variations to the normal sequence of the gall bladder shadow as it appears after the administration of the dye. These may be enumerated in their order of importance as follows:

- 1 Absence of shadow
- 2 Persistency of shadow
- 3 Faintness of shadow
- 4 The late appearance of the shadow

1 *Absence of Shadow*—Any obstruction to the cystic duct either from an intrinsic or extrinsic cause will prevent the opaque bile from entering the gall bladder giving a "no shadow" finding. Most common cause of obstruction is from a stone or stones, stricture of the cystic duct will obviously give the same finding. Obliteration of the lumen of the gall bladder, the result of an old chronic inflammation or a gall bladder packed with stones, will also fail to give a shadow. One must not forget that impaired liver function may fail to provide sufficient opaque bile to cast a shadow.

It is well to pass on a word of warning in "no shadow" cases. Always confirm the findings by a reexamination to be sure it is not due to some fault in the technique.

2 *Persistency of Shadow*—When the shadow of the gall bladder does not markedly diminish

in size after food and persists thirty-six hours after the administration of the dye we may reasonably conclude that the normal function is interfered with by pathology. This deduction has been repeatedly proven to be correct by the surgical findings of chronic cholecystitis in these cases.

3 *Faintness of Shadow*—When one has perfected and standardized the technique to such an extent that it can absolutely be relied upon then the finding "faintness of shadow" is of great importance, for it means a disturbance to the concentrating power of the gall bladder caused by chronic inflammation. "Faintness of shadow" is often associated with "persistency of shadow," the causative factor being much the same. Faintness of shadow and mottling are the two most treacherous findings. Be extremely careful in these interpretations. Do not hesitate to make a confirmatory examination.

4 *Late Appearance of the Shadow*—This rather rare finding must be mentioned, for in a number of cases in our series the gall bladder shadow did not appear until thirty-six hours after the dye was given. All were proven to be pathological.

It is interesting to note that in some cases in which gall stones are visualized by the test the gall bladder still shows fairly good function.

In no instance should he neglect to examine the gastrointestinal tract, many times the supporting evidence of duodenal or intestinal adhesions to the gall bladder confirms what may have been a questionable diagnosis. All cases referred to us for gall bladder examinations have the stomach and colon gone over after the completion of the tetraiodo test.

We have already spoken in other communications of the great value of visualizing the gall bladder in the differentiation between nephro and chole lithiasis. Is it much simpler and less distressing to the patient to map out the gall bladder by opaque bile than it is to outline the kidney, pelvis and calices by pyelography, in either case we should be able to make the differentiation.

This paper is based on observations made on clinical cases, all examined by the oral method.

PRURITUS* CAUSES, EFFECTS AND TREATMENT

By S POLLITZER, NEW YORK, N Y

I AM to discuss this evening the subject of itching. When we use a Latin word *pruritus* instead of the common English term, we do not thereby change the character of the affection. *pruritus* remains merely a symptom and it is not a disease in itself. Itching regularly accompanies a large variety of skin diseases—eczema, lichen planus, scabies, pediculosis, etc.—but for convenience we restrict the term *pruritus* to that disturbance in cutaneous sensation in which there is apparently no preceding or primary disease of the skin. We speak then of essential *pruritus*.

Essential *pruritus* may be defined as a chronic intermittent sensory neurosis dependent on an abnormal excitation of tactile sense-organs apparently not related to any preceding organic change in the skin. The question at once arises whether or not the term essential as thus used is not merely a cloak to our ignorance, whether there is not in every case of itching a physical or chemical change in the skin too subtle for our gross methods of observation. While perhaps most cases of *pruritus* are dependent on such delicate changes in the skin that they cannot be recognized, we know that disorders of the central nervous system are capable of giving rise to itching just as they more commonly occasion other cutaneous paresthesias. The neurological literature contains many illustrations of the central origin of *pruritus*. Unilateral itching has been noted in cases of central embolus with paraplegia, an intractable *pruritus* at the beginning of a progressive paralysis, etc. Still more striking are those cases of itching which are purely psychic in their origin, as when a whole class of medical students will begin to itch during the clinical demonstration of a case of pediculosis, where the possibility of a disorder in the skin itself seems out of the question. Equally convincing for the existence of *pruritus* without local changes in the skin seems to be the reflex itching to which we shall refer later.

On the other hand, it cannot be denied that the *pruritus* of apparently central origin may be due to local changes in the skin brought about by motor impulses affecting the local circulation or the cutaneous muscles, the *arrectores pilorum*. Flushing or blanching of the skin is a common accompaniment of central lesions and of psychic impressions, and goose flesh, *cutis horrida*, is often the resultant of a mental state. These considerations serve to illustrate some of the difficulties and complexities of the problem of the pathogenesis of itching. Regarded in this light the occurrence of *pruritus* of central origin may be explained as only indirectly of central origin, the nerve centers producing local disturbances in

the skin through the intervention of the motor apparatus. The *pruritus* of central origin would thus be brought into the large group of cases in which the symptom is provoked by mechanical irritation.

Mechanical irritation, irritation of the sensory end-apparatus in the skin, is, it is well known, a common cause of itching. A simple experiment made by Hebra, half a century ago, illustrates the relation of itching to mechanical stimuli. When the skin is gently stroked as with a feather, a sensation of tickling is experienced. If the stroking is continued the tickling after a time passes over into a sensation of itching. This experiment is one of fundamental importance for our ideas of the pathogenesis of *pruritus*. It establishes the fact that itching may be provoked by long continued gentle stimulation of the superficial tactile nerves. It affords an immediate explanation of all that large group of cases of *pruritus* in which the itching is provoked by prolonged mild external irritation as from woolen clothing, and it offers a possible explanation of the itching that arises from exposure of the warm skin to the colder air of the bedroom. Circulatory changes in the skin or stimulation of the *arrectores pilorum* may serve as the immediate source of the irritation of the cutaneous nerves.

An obvious objection to this explanation of the pathogenesis of itching in such cases at once presents itself in the circumstance that these causes are operative in only a very small number of people. Most people do not itch on removing their clothing, not even when they experience the contraction of the hair-muscles producing goose-skin. We are forced to the conclusion that there is in these cases of *pruritus* another factor, and this factor may be found in the assumption of a hyperesthesia of the tactile nerves which underlies every case of *pruritus*. The cause of this hyperesthesia must be sought in some chemical change of the blood.

There is a large group of cases of *pruritus* commonly associated with systemic diseases in which some noxious substance is present in the blood. I need only mention icterus, diabetes, albuminuria, tuberculosis, cancer, mycosis fungoides, the leucaemias, chronic intestinal disorders, helminthiasis, etc. In this category too we may place the *pruritus* following the use of various drugs—morphine, belladonna, arsenic, etc. In all these conditions there are toxic substances in the system which reach the cutaneous nerve ends by way of the blood-stream and there acting continuously over long periods bring about that hyperesthesia which readily may pass into the sensation of itching. It seems a reasonable deduction from these well-known facts to assume that in every case of general *pruritus* there are

* Read before the New York Academy of Medicine, January 21, 1926

chemical substances in the blood, for the most part unknown in their nature and origin, which serve to sensitize the cutaneous nerves. This hypothesis of a prerequisite chemical change in the blood in chronic pruritus is fortified by the circumstance that itching produced by mechanical irritation as in the Hebra experiment, which may be regarded as a physiological pruritus, ceases when the tickling is stopped.

We may digress here a moment to consider the itching in certain common skin diseases, such as eczema and scabies. It is often assumed that the itching in these cases is due to the exposure of nerve ends resulting from the vesicles of eczema or the burrowing of the acarus. But exposure of cutaneous nerve ends does not in itself cause itching. The superficial layers of the epidermis may be removed entirely as by a traumatic abrasion or by the blister of a second-degree burn, and yet this denuded area does not itch. There is, however, in the cases of eczema, scabies, etc., a local toxic element, the product of the activity of infecting germs in the eczemas, or of the acari in scabies. It is of course true that there are lesions of the skin accompanied by itching which are not caused by local infection. So, for instance, lichen planus in which we have sometimes a most intense pruritus. It is true that in this disease we find all degrees of itching, some cases itching, but moderately and some not at all. It would seem a hopeless task to seek the cause of itching in a disease of whose real nature we know nothing, one moreover in which the symptom of itching may be present or may be absent. It is conceivable, however, that the itching in this disease belongs in the category of pruritus from prolonged mechanical irritation. In lichen planus there is a dense cellular infiltration, especially involving the interfollicular areas of the skin and often terminating at the side of a follicle. These structures, the hair follicles, are surrounded by a close network of the finest nerve fibres which makes each hair, in a peculiar sense, a tactile organ, the relatively firm structure of the projecting hair serving as a lever-arm to convey exaggerated sensory impressions to the nerve fibres which surround its root sheath. The papillary infiltration may disturb the normal relations of the hair-follicle nerves and acting as a continuous source of irritation bring about the pruritus which, moreover, will vary in degree in different cases with the precise location of the infiltration in relation to the hair follicles.

In somewhat the same way we may explain the itching that as a matter of common experience accompanies the healing of a wound under a scab by secondary intention. The relatively inelastic crust creates abnormal conditions of pressure and tension in the area affected and is thus the source of the continuous mild tactile irritation which we have seen to be a cause of itching. These speculations cannot, I am well aware, be

regarded as demonstrated truths, but they may have a certain value in simplifying our ideas of the causes of itching, in reducing the apparently complex and heterogeneous sources of pruritus to lower terms.

The degenerative changes that take place in the senile skin are commonly regarded as a cause of itching. We speak in fact of a senile pruritus. It seems to me very questionable whether the changes that take place in the skin in old age are in themselves capable of producing itching. In the first place, everyone who does not die too soon, reaches old age, and pruritus is happily by no means inevitable in the aged. We are all acquainted with old people whose dry, wrinkled, atrophic skin gives them no trouble at all. On the other hand, there are severe cases of pruritus in the aged whose skin is smooth and well nourished. Old age is especially prone to degenerative changes in important organs whose malfunction results in the occurrence and accumulation of toxic substances in the blood. I need only mention the kidneys, the liver and the glands of internal secretion. From this point of view, itching in old people falls into the category of pruritus from toxæmia, and the term senile pruritus is inappropriate.

Among common disorders in the aged are those arising from degenerative changes in the arteries. General pruritus is sometimes observed in the arteriosclerotic. While it is possible that the sclerotic processes may affect the cutaneous blood vessels in such a way as to bring about disturbed relations of an irritative character to the cutaneous nerve ends, it seems to me far more probable that it is the disorders of important viscera, due to the arteriosclerosis which affects them and results in the accumulation of toxic substances in the blood, to which the pruritus must be ascribed.

Localized itching associated with a definite disorder of one of the viscera, is often assumed to be of reflex origin. Diseases of the rectum, of the prostate, a stone in the bladder, or in the pelvis of the kidney, pregnancy and uterine disorders, are supposed to be the cause of irritative processes which are reflected on the skin of the anal, perineal or pudendal region as a pruritus. While many of these cases, perhaps the majority, are undoubtedly caused by toxic or autotoxic processes, the possibility of their origin in continuous local irritation at the visceral site of the disorder, cannot be excluded. We must assume then that this local visceral irritation is transmitted to the spinal ganglia, passed on to the sensorium and there referred to the cutaneous ends of the nerves supplying associated areas in the skin. Sensations of heat, pain and various paresthesias in the glans penis from prostatic disease and in the upper inner portion of the thighs from renal diseases is a well established clinical fact. A

modification of the original stimulus, may, we can readily understand, give rise to itching

Itching at the anus, perineum and the pudenda constitutes the most commonly encountered form of local pruritus. It is precisely in this portion of the integument that the opportunities for local infection are most abundant. Whether the disorder has its inception as a pure reflex neurosis or not is of little practical importance. The itching is immediately followed by friction or scratching with the inevitable result of local infection of the affected area. In actual practice we never encounter uncomplicated cases of pruritus of the anal and pudendal regions, but invariably those changes in the structure of the skin which are brought about by attempts to relieve the itching. In recent years, it is especially Winfield and Montague who have made valuable studies on the bacteriology of so-called pruritus of the anus and perineum. In far the greater number of cases of this kind the pruritus, as we see it, is due to eczema caused by infection. An infinitesimal tear at the anal ring produced by abnormally hard feces, or by friction with toilet paper, or the congestion and consequent moisture at the anus due to hemorrhoids may be the starting point of an infectious eczematous process, or in the case of vulval pruritus, friction following the slight irritation of a leucorrhoeal secretion, may initiate the disease. A drop of urine, especially diabetic urine, by affording a better soil for the growth of bacteria and fungi may serve as the original cause of the infection.

One of the most common effects of pruritus is the development, in circumscribed or more extensive areas, of the secondary changes in the skin which we call lichenization, constituting the lichen circumscriptus chronicus of Vidal. In this condition which we find most frequently on the labia, the upper inner portion of the thighs, on the back of the neck in women, on the acrotum and at the anus in men, the skin is dry and greatly thickened in the affected areas. On inspection we find that the hypertrophy is due to a thickening of the normal cuticular areas and at the periphery of the patch such hypertrophied fields resembling lichen planus papules may be seen. This is the disease formerly known as chronic circumscribed eczema. While it is not a constant and inevitable sequence of localized pruritus, pruritus is a necessary antecedent of the condition. For an understanding of the process we must assume a systemic disturbance, toxic or auto-toxic, which sensitizes the cutaneous nerves. The itching may be initiated by anyone of a host of minor accidents, the sting of an insect, the drying of a drop of secretion, etc., or it may fall into the category of reflex itching. The friction which is the immediate response to the itching causes a local hyperæmia which results in a pouring out of lymphocytes. The local structural changes in turn aggravate the itching which causes more scratching, which again

aggravates the local structural changes. And so we enter into a vicious circle: itching, scratching, exudation, more scratching, more exudation, more itching. The underlying cause of this disorder is a vice of the system affecting some chemical change in the blood. It is frequently dependent on intestinal, especially colonic disorders, it is often the effect of disturbances in the endocrine balance. It is far more frequent in women than in men, and is often associated with menstrual irregularities, especially with the irregularities at and following the menopause.

To sum up these views on the etiology of chronic pruritus, I should say that this symptom depends in general on the presence of some toxic products in the blood and, in a small number of cases of localized pruritus it may be the transferred cutaneous expression of visceral irritation. Whether of toxic or of reflex neurotic origin the recurrent attacks of itching require for their inception some local disturbance in the skin affecting if only momentarily a change in the circulation or in the cutaneous muscles. These local, for the most part, insignificant disturbances, derange the harmonious balance of cutaneous sensation and serve in the sensitized as the trigger which discharges the pruritic attack.

The local effects of pruritus are those which result from the hyperæmia of prolonged friction and from local infection. The pruritic skin is always thickened and more or less excoriated. In small areas as in the ano-genital region we constantly find the secondary effects of the itching, —eczematization or lichenization. The systemic effects of the disorder vary with the severity and frequency of the attacks. In bad cases the patient, losing all restraint, tears and excoriates the skin, the scratching being accompanied by a voluptuous sensation, and it is only when the skin is raw and streaming with blood that the pale and exhausted victim finds relief. Such attacks lasting five to fifteen minutes or longer may recur several times in a night. It is obvious that these repeated nerve-storms together with the resulting loss of sleep must have a severely depressant effect on the system. In children pruritus is always associated with urticaria or with the papular lesions we call prurigo. Strictly speaking these conditions should be considered with pruritus, but the invariably association with these morphological changes in the skin, somewhat illogically takes them out of the class of cases which we are discussing here.

In the treatment of pruritus we cannot expect a permanent cure unless we can remove the cause. It is needless to emphasize the importance of a careful clinical examination. Urine, feces and blood must be examined, a pruritus may be the first symptom of a visceral cancer or of a leucæmic disease. Even the mouth and teeth should not be neglected. In reflex pruritus the removal of a stone in the bladder or the kidney, of a pelvic

infiltrate, etc., will be the first step in the cure of the itching. Where the systemic causes are toxic, resulting from organic diseases of the liver, kidneys etc., the treatment will afford relief only when the underlying organic disease can be cured or mitigated. I have had excellent results from the administration of ovarian substance in pruritus following the menopause. It is the class of cases in which the toxic products in the blood are the result of abnormal chemical processes in the gastro-intestinal tract that offer our best field for therapeutic efforts. In the majority of cases of this kind while we may not be able to specifically determine the nature of the abnormal processes, benefit may be obtained from a radical change in the diet. Such change of diet may be indicated by the symptoms of abnormal fermentative processes, of a catarrhal enterocolitis or by constipation. In the absence of direct indications it is often of advantage on purely empirical grounds to put the patient on a strict vegetable diet. The chemistry of the intestinal tract may be favorably altered by colonic irrigations and implantation, or by the administration of large quantities of bacillus acidophilus cultures. Sedatives and especially narcotics should be absolutely interdicted.

Whatever the results of our attempts at determining and removing the systemic causes of the pruritus, local measures directed to the skin are of almost equal importance. From what has been said on the effects of friction and the cycle of itching, scratching, local changes and more itching, it is evident that efforts must be directed to relieving the cutaneous symptom. To this end we must in the first place, enlist the aid of the patient. He must make every effort to control the impulse to scratch. The mental attitude of the patient towards his itching is of importance. Klauder, of Philadelphia, has recently published

an interesting series of cases in which the pruritus of neurotic origin was cured by psychotherapy.

We possess a large series of remedies for the symptomatic relief of itching. The patient's skin should be protected against external contacts and temperature changes which precipitate an attack through disturbance of the lanugo hairs. Swathing the patient in cotton wool has been employed with benefit, better and simpler is to cover the entire integument with a layer of Unna's glycerine-zinc-gelatine. As a rule, lotions containing phenol, tar and menthol in very small percentages, are preferable to salves, but the remedies mentioned may be incorporated in an ointment when the patient's skin seems abnormally dry.

Bathing often provokes an attack, the occasional bath should be tepid and a pound or two of bicarbonate of soda, a bran bag and perhaps a few ounces of an alkaline tar solution may be added with advantage. Friction with a towel must be avoided. Ordinary soaps are harmful in most cases and only a superfatted soap should be permitted. Perhaps the most effective of local antipruritic measures is irradiation with the Roentgen rays in quarter-unit doses once a week when the involved areas are limited in extent, or better still, in my experience, with ultra-violet light in suberythema doses over the entire integument when necessary, two or three times a week. The relief is usually striking and immediate and lasts a day or two. Needless to say the secondary effects of the itching, the eczematization and lichenization of the skin must be removed by appropriate local measures if the cure is to be complete.

When all is said, we must admit that there are a great many cases of pruritus which are absolutely refractory to our efforts, but it is certain that many can be cured and to all we can promise at least some measure of relief.

modification of the original stimulus, may, we can readily understand, give rise to itching

Itching at the anus, perineum and the pudenda constitutes the most commonly encountered form of local pruritus. It is precisely in this portion of the integument that the opportunities for local infection are most abundant. Whether the disorder has its inception as a pure reflex neurosis or not is of little practical importance. The itching is immediately followed by friction or scratching with the inevitable result of local infection of the affected area. In actual practice we never encounter uncomplicated cases of pruritus of the anal and pudendal regions, but invariably those changes in the structure of the skin which are brought about by attempts to relieve the itching. In recent years, it is especially Winfield and Montague who have made valuable studies on the bacteriology of so-called pruritus of the anus and perineum. In far the greater number of cases of this kind the pruritus, as we see it, is due to eczema caused by infection. An infinitesimal tear at the anal ring produced by abnormally hard feces, or by friction with toilet paper, or the congestion and consequent moisture at the anus due to hemorrhoids may be the starting point of an infectious eczematous process, or in the case of vulval pruritus, friction following the slight irritation of a leucorrhoeal secretion, may initiate the disease. A drop of urine, especially diabetic urine, by affording a better soil for the growth of bacteria and fungi may serve as the original cause of the infection.

One of the most common effects of pruritus is the development, in circumscribed or more extensive areas, of the secondary changes in the skin which we call lichenization, constituting the lichen circumscriptus chronicus of Vidal. In this condition which we find most frequently on the labia, the upper inner portion of the thighs, on the back of the neck in women, on the acrotum and at the anus in men, the skin is dry and greatly thickened in the affected areas. On inspection we find that the hypertrophy is due to a thickening of the normal cuticular areas and at the periphery of the patch such hypertrophied fields resembling lichen planus papules may be seen. This is the disease formerly known as chronic circumscribed eczema. While it is not a constant and inevitable sequence of localized pruritus, pruritus is a necessary antecedent of the condition. For an understanding of the process we must assume a systemic disturbance, toxic or auto-toxic, which sensitizes the cutaneous nerves. The itching may be initiated by anyone of a host of minor accidents, the sting of an insect, the drying of a drop of secretion, etc., or it may fall into the category of reflex itching. The friction which is the immediate response to the itching causes a local hyperæmia which results in a pouring out of lymphocytes. The local structural changes in turn aggravate the itching which causes more scratching, which again

aggravates the local structural changes. And so we enter into a vicious circle: itching, scratching, exudation, more scratching, more exudation, more itching. The underlying cause of this disorder is a vice of the system affecting some chemical change in the blood. It is frequently dependent on intestinal, especially colonic disorders, it is often the effect of disturbances in the endocrine balance. It is far more frequent in women than in men, and is often associated with menstrual irregularities, especially with the irregularities at and following the menopause.

To sum up these views on the etiology of chronic pruritus, I should say that this symptom depends in general on the presence of some toxic products in the blood and, in a small number of cases of localized pruritus it may be the transferred cutaneous expression of visceral irritation. Whether of toxic or of reflex neurotic origin the recurrent attacks of itching require for their inception some local disturbance in the skin affecting if only momentarily a change in the circulation or in the cutaneous muscles. These local, for the most part, insignificant disturbances, derange the harmonious balance of cutaneous sensation and serve in the sensitized as the trigger which discharges the pruritic attack.

The local effects of pruritus are those which result from the hyperæmia of prolonged friction and from local infection. The pruritic skin is always thickened and more or less excoriated. In small areas as in the ano-genital region we constantly find the secondary effects of the itching, —eczematization or lichenization. The systemic effects of the disorder vary with the severity and frequency of the attacks. In bad cases the patient, losing all restraint, tears and excoriates the skin, the scratching being accompanied by a voluptuous sensation, and it is only when the skin is raw and streaming with blood that the pale and exhausted victim finds relief. Such attacks lasting five to fifteen minutes or longer may recur several times in a night. It is obvious that these repeated nerve-storms together with the resulting loss of sleep must have a severely depressant effect on the system. In children pruritus is always associated with urticaria or with the papular lesions we call prurigo. Strictly speaking these conditions should be considered with pruritus, but the invariably association with these morphological changes in the skin, somewhat illogically takes them out of the class of cases which we are discussing here.

In the treatment of pruritus we cannot expect a permanent cure unless we can remove the cause. It is needless to emphasize the importance of a careful clinical examination. Urine, feces and blood must be examined, a pruritus may be the first symptom of a visceral cancer or of a leucæmic disease. Even the mouth and teeth should not be neglected. In reflex pruritus the removal of a stone in the bladder or the kidney, of a pelvic

THE CIVIC ACTIVITIES OF COUNTY MEDICAL SOCIETIES

The Secretaries' Conference on September 2 revealed a considerable degree of misapprehension concerning the relation between county medical societies and lay organizations engaged in public health (see this JOURNAL, September 15, page 798). The direct question was asked "Has any medical society invited representatives of lay organizations to speak before the society's meeting?" It brought out the fact that very few societies had done so, but on the contrary, there was an undercurrent of feeling that the relation between the medical societies and the lay organizations was not entirely harmonious, and that many medical societies did not wish to be closely allied with lay health organizations.

The editorial pages of this JOURNAL have recently set forth the need of a closer relation between the three groups of public health workers, so that each shall do the work that properly belongs to it. An editorial on "The County Medical Society in Public Health" in the JOURNAL of May 15, page 473, set forth the historical development of the three great groups of organizations engaged in public health—Departments of Health, lay health organizations, and medical societies—and showed how out of the experience and attempts of various plans by the three groups, there had developed a clear conception of a practical way to co-ordinate the activities of the groups into a harmonious trinity with the physician group leading and advising the other two.

The same idea was further developed in an editorial in the July first issue, page 615, which partially outlined the proper fields of work of the three groups of public health workers. The broad principles of the diagnosis of the public health situation have been clearly defined, and are accepted by all the groups, and the next step is to apply them to individual communities.

The Secretaries' Conference showed that the attitude of many doctors is that they consider almost the entire function of a County Medical Society is to carry out scientific programs on curative medicine. But the scope of the activities of organized medicine is much broader.

A modern county medical society has duties along three lines: 1, the personal benefit of its members—mutual protection and sociability; 2, instruction of its members in scientific medicine; and 3, the practice of civic medicine.

The social side of county medical societies is well developed in the form of lunches and of testimonial dinners to the older members. What this means to physicians may be appre-

ciated when there are recalled the public disputes and open antagonisms among doctors a generation or two ago. The meetings of county societies are great promoters of friendships and cooperation among doctors. Several secretaries at the conference said that their best meetings were friendly dinners given their older members. Sociability among doctors is not a form of mere selfish enjoyment, it is a public health measure of which the people receive benefit in the cooperation among physicians and their exchange of ideas.

The instruction of physicians in scientific medicine has always been a major function of county medical societies, and no program is considered complete unless it includes a paper on some phase of the practice of medicine. Instruction in scientific medicine received a great impetus during the past year owing to the courses of lectures and study promoted by the State Society in co-operation with the State Department of Health. The majority of secretaries at the conference approved the courses in pediatrics and obstetrics, for these subjects were practical and the instruction could be put to use in the daily practice of medicine.

Regarding the third function of a county medical society—that of practising civic medicine—there was considerable difference of opinion at the Secretaries' Conference. One secretary said that his society had been "Fed up" with public health to such an extent that the members stayed away from the meeting when the subject was made prominent in the programs. Others said they did not invite public health workers to attend the society meetings. When these misunderstandings and antagonisms exist, it would seem that there was something wrong with the brand of public health that was presented to the doctors, or that the doctors did not recognize the virtue of practicality in the public health work of lay organizations.

Doctors have always insisted that the medical profession should be the advisor of the community in all health matters. But physicians have held themselves aloof from "Practical politics," and have waited for their advice to be asked, before they have expressed an opinion on any community problem. They have felt that the community should seek their advice, and that to offer unsolicited advice to a community was as unethical as to force it upon an individual unasked.

The modern standard of action is that the county medical society represents "the Medical Profession," and that its duty is to give voice to the collective opinions of its individual members. While one individual doctor might seem to be advertising himself when he

PROGRAMS OF MEDICAL SOCIETIES

The programs of the meeting of the State Medical Society and its component societies reflect the newer items of medical progress, especially those phases of medicine which are practiced by family doctors. General practitioners are expected to advise their communities as well as their patients. How they may discharge their civic duties has become a subject of increasing interest, although public health topics have often not been popular in

the programs of county medical societies. Every number of the program of the meeting of the Sixth District Branch was on the subject of public health and civic medicine and specifically consisted largely of reports of the actual practice of civic medicine by the county societies of the District. (See report on page 836.) The attention shown to the speakers was abundant evidence of the interest of physicians in practical phases of public health and civic medicine.

these were the agents by which the new word was carried to the profession all over the country. Officially speaking (U S Civil Service Commission Circular Notice No 50, Assembled, issued January 2, 1924), it "will consist of massage, electrotherapy, hydrotherapy, mechanotherapy, thermotherapy, active, passive, resistive and assistive exercises and remedial gymnastics." Under electrotherapy are, of course, included actinotherapy and radiotherapy.

It naturally followed that the doctor in charge of a physiotherapy clinic should become known as a "physiotherapist." He was a commissioned officer skilled in the subject, usually a Fellow of the American Electrotherapeutic Association, with its quarter century of development in this field. Additional medical officers were trained by him to act as assistants, or to take charge of like departments at other centers, and some still continue as such in Army and Veterans' Bureau hospitals and clinics.

Physiotherapy aides, the official name for non-medical assistants in those hospitals, were obtained, late in 1917, by a coast-to-coast canvas of women's colleges. Over 870 were selected, among 5,000 volunteers from this source, for three months' intensive training courses, however, with dismantling of these hospitals, most of this fine type of personnel have returned to their prewar callings. Physicians employing such assistants at the present day in office or hospital view them as "physiotherapy technicians" (akin to X-ray technician or laboratory technician). The word "technician" is now preferred as more definitely explanatory of the paid employee than that of "aide," the latter being too suggestive of "volunteer" and, therefore, unsuited to civilian practice.

The effective work of these college-bred girls and their good influence on the morale of patients (as may also be said of some of the young men assistants taken from the ranks) having

won high praise for such service, many less worthy imitators have since then tried to capitalize this reputation. Chiropractors and other get-smart-quicks are among the Ishmaelites who would thus benefit—and some few physicians, none the wiser, unfortunately recommend them to patients or even themselves at times employ them.

The provision in the new Medical Practice Act by which laymen are designated as "physiotherapists" is certainly an unfortunate one in that the suffix "ist," in a word applied to illness or injury, has always heretofore signified a medical graduate. Neurologist, otologist, gynecologist, these are familiar examples. Until finally become a specialist in medicine, dentist is perhaps the sole exception to the rule—although its synonym, stomatologist, is invariably a medical practitioner. So that "physiotherapy technician" should have been substituted for "physiotherapist" in that part of the new act.

Quite naturally, some resentment was felt by physicians trained in this field at the bold attempt of laymen to appropriate a title clearly indicating the medical graduate, the State Department of Education, however, will find few if any prospective lay applicants fitted to meet the high educational requirements of the proposed position. The danger from the situation is for the people of other states, those with more liberal (?) laws and more pliant officials, in that enough untrained laymen (with the physiotherapist provision in the New York law serving them as a precedent) may appropriate the title, form one more objectionable cult and obtain state sanction from their "easy" legislators.

It therefore behooves physicians of the State to keep posted on the situation. Further legislation is undoubtedly indicated to control the training of young men and women planning to act as their assistants, in office and hospital, in this rapidly growing branch of our therapeutics.

HEALTH QUESTIONS ASKED BY LAYMEN

The health columns in magazines and daily papers reflect the kind of medical advice which is sought by laymen. Most of the items are replies to questions submitted by persons who are sincerely anxious over medical problems. Will Blank's reducing soap remove fat from my double chin? Is sugarene a safe remedy for diabetes? Is brisk exercise before breakfast good for anyone with a weak heart? These are samples of questions that are put to doctors by anxious inquirers.

What are the doctors' answers to these inquiries? Usually they are plain denials of the efficacy of the suggested therapeutics. But negative replies are not satisfying, and the inquirers seek for some one who will give the

answer that the questioners wish to hear. But why does the dictum of medical authority fail to carry universal conviction? The history of medical discoveries furnishes an important clue to the answer.

The essence of medical progress is a constant questioning of both evidence and conclusions. The great discoveries in medicine have come after hundreds of clues have been tested and found baseless. Surgical asepsis was violently opposed by the leading obstetricians and operators in the early eighties, and leading pediatricians persisted in their opposition to diphtheria antitoxin long after its efficacy was accepted by the majority of physicians. If anyone is seeking for the evidence of disagree-

expresses his private opinion regarding a health subject, he is entirely ethical and praiseworthy when he speaks after he has been authorized to do so by his county society. The machinery for expressing the views of the medical profession is now available and ethical methods of its application are standardized and almost universally accepted by physicians.

Giving opinions concerning the health phases of community topics is the essence of the practice of civic medicine. This practice is much broader than the practice of public health, or the practice of preventive medicine by welfare organizations. It includes advice in such topics as public supplies of milk and water, the disposal of sewage, and the control of communicable diseases, with which departments of health deal, it embraces the subjects of baby welfare, medical school inspection and anti-tuberculosis work which are often monopolized by welfare organizations, it covers the health phases of the subjects of child labor, workmen's compensation and the prevention of automobile accidents, whose control is plainly the responsibility of office holders, it is included in the subject of the health education of the people — what to do in emergencies, how to care for the baby, and the value of vaccines, it is intimately connected with the subject of charity — the building and management of hospitals and the mutual relation between poverty and ill-health.

Some of these subjects are always before the people for discussion and office holders for solution in the territory of every county medical society, and the people expect the doctors—that is, the county medical society — to express their opinion regarding them. But physicians have often permitted the authority to pass to welfare organizations. It is only natural that amateurs in the practice of any branch of medicine should advance impractical plans, and should be impatient with the practitioners of scientific medicine who disapprove of their radical views. Community health problems cry out for solution in every county, and the only group that can solve them is the medical practitioners who know their communities intimately.

Every county society has the opportunity to assert itself in some problem of civic medicine which is prominently before the people. When it expresses its opinion, it is practising civic medicine. The Tioga County Medical Society, for example, is setting an excellent example to the other county societies as it supervises and controls the activities of two public health nurses whose work is principally prenatal and obstetrical.

If each county medical society would take up some civic problem that is occupying the attention of the community, it would fulfill its function in public health and civic medicine, and would gain the support of both the physicians and the people.

PHYSIOTHERAPY, HISTORY AND EXPLANATIONS

WITH signature of the Webb-Loomis Bill by Governor Smith on May 17 the general public of the State were given a Medical Practice Act that, faithfully enforced, safeguards it against the horde of shameless "healers" who for years have fattened on their otherwise unprotected victims. Consequent transfer of prosecution of these criminals from county officials to those of the attorney general's office should give assurance of more continuous aggressive pressure to drive the cultists from the State. Not the least important is the provision for annual reregistration of physicians, one calling for but little effort by the latter, but among the most practical measures for singling out lawless healers in the community. So, too, will action under our profession's control to discipline culprits within its own ranks do much to increase public regard for the ethical doctor everywhere.

But how about that provision for laymen to function as physiotherapists in the newly enacted law? And why should insertion of this eleventh hour amendment have aroused such determined objection by medical practitioners specially

trained in use of the newer physical treatment methods? The feeling aroused was unmistakable that someone had blundered in letting this unwarranted provision creep in. To grasp the meaning of it all, physicians should clearly understand exactly what is included under those new terms, physiotherapy and physiotherapist.

When did "Physiotherapy" originate and how shall we define it? Widespread addition of these newer physical remedies to surgery, pharmacals, and other treatment facilities followed their extensive use in army hospitals of the recent war. When planning these large hospitals, army authorities, acting on suggestion of those in the American Electrotherapeutic Association, took heed of the good results achieved abroad, and then installed much new equipment for the purpose. A comprehensive, euphonious term for these methods was lacking so that, after due study, "physiotherapy" was the word then coined. The Navy, the Public Health Service and especially the Veterans' Bureau (the latter now the most extensive employer of these physical methods and its trained medical and lay personnel)—

these were the agents by which the new word was carried to the profession all over the country. Officially speaking (U S Civil Service Commission Circular Notice No 50, Assembled, issued January 2, 1924), it "will consist of massage, electrotherapy, hydrotherapy, mechanotherapy, thermotherapy, active, passive, resistive and assistive exercises and remedial gymnastics." Under electrotherapy are, of course, included actinotherapy and radiotherapy.

It naturally followed that the doctor in charge of a physiotherapy clinic should become known as a "physiotherapist." He was a commissioned officer skilled in the subject, usually a Fellow of the American Electrotherapeutic Association, with its quarter century of development in this field. Additional medical officers were trained by him to act as assistants, or to take charge of like departments at other centers, and some still continue as such in Army and Veterans' Bureau hospitals and clinics.

Physiotherapy aides, the official name for non-medical assistants in those hospitals, were obtained, late in 1917, by a coast-to-coast canvas of women's colleges. Over 870 were selected, among 5,000 volunteers from this source, for three months' intensive training courses, however, with dismantling of these hospitals, most of this fine type of personnel have returned to their prewar callings. Physicians employing such assistants at the present day in office or hospital view them as "physiotherapy technicians" (akin to X-ray technician or laboratory technician). The word "technician" is now preferred as more definitely explanatory of the paid employee than that of "aide," the latter being too suggestive of "volunteer" and, therefore, unsuited to civilian practice.

The effective work of these college-bred girls and their good influence on the morale of patients (as may also be said of some of the young men assistants taken from the ranks) having

won high praise for such service, many less worthy imitators have since then tried to capitalize this reputation. The provision in the new Medical Practice Act by which laymen are designated as "physiotherapists" is certainly an unfortunate one in that the suffix "ist," in a word applied to illness or injury, has always heretofore signified a medical graduate. Neurologist, otologist, gynecologist, these are familiar examples. Until finally become a specialist in medicine, dentist is perhaps the sole exception to the rule—although its synonym, stomatologist, is invariably a medical practitioner. So that "physiotherapy technician" should have been substituted for "physiotherapist" in that part of the new act.

Quite naturally, some resentment was felt by physicians trained in this field at the bold attempt of laymen to appropriate a title clearly indicating the medical graduate, the State Department of Education, however, will find few if any prospective lay applicants fitted to meet the high educational requirements of the proposed position. The danger from the situation is for the people of other states, those with more liberal (?) laws and more pliant officials, in that enough untrained laymen (with the physiotherapist provision in the New York law serving them as a precedent) may appropriate the title, form one more objectionable cult and obtain state sanction from their "easy" legislators.

It therefore behooves physicians of the State to keep posted on the situation. Further legislation is undoubtedly indicated to control the training of young men and women planning to act as their assistants, in office and hospital, in this rapidly growing branch of our therapeutics.

HEALTH QUESTIONS ASKED BY LAYMEN

The health columns in magazines and daily papers reflect the kind of medical advice which is sought by laymen. Most of the items are replies to questions submitted by persons who are sincerely anxious over medical problems. Will Blank's reducing soap remove fat from my double chin? Is sugarene a safe remedy for diabetes? Is brisk exercise before breakfast good for anyone with a weak heart? These are samples of questions that are put to doctors by anxious inquirers.

What are the doctors' answers to these inquiries? Usually they are plain denials of the efficacy of the suggested therapeutics. But negative replies are not satisfying, and the inquirers seek for some one who will give the

answer that the questioners wish to hear. But why does the dictum of medical authority fail to carry universal conviction? The history of medical discoveries furnishes an important clue to the answer.

The essence of medical progress is a constant questioning of both evidence and conclusions. The great discoveries in medicine have come after hundreds of clues have been tested and found baseless. Surgical asepsis was violently opposed by the leading obstetricians and operators in the early eighties, and leading pediatricians persisted in their opposition to diphtheria antitoxin long after its efficacy was accepted by the majority of physicians. If anyone is seeking for the evidence of disagree-

ment over essential facts in medicine, he can find it in the rejection of every medical discovery by some prominent doctors

Physicians, like sick people, are prone to believe and to try every new thing that appears to be a short cut to success, and also to reject those which require high skill and knowledge in their application. The promoters of visionary remedies and sure health restorers are found among both physicians and laymen

This is an age of questioning authority in every line of human thought, and fame or notoriety comes from the most unpromising

sources. Whatever is talked about will be accepted as truth by a sufficient number of persons to enable its promoters to capitalize the idea regardless of its truth or falsity. What matters it to the promoters that ninety-nine per cent of the people condemn their schemes provided one per cent support them with their dollars? One per cent of the people of the United States makes 1,100,000 persons—a tremendously big number, yet only a small per cent of the total population

Doctors need not be pessimistic over the quack situation, for ninety-nine per cent of the people give them their faith and confidence

LOOKING BACKWARD

THIS JOURNAL TWENTY-FIVE YEARS AGO

President William McKinley was shot about 3 45 o'clock on September 6, 1901, through the stomach and pancreas, while he was attending the Pan-American Exposition in Buffalo. An operation was performed about six o'clock. Death occurred on September 14

A prominent physician has recently stated his experience at the time of the shooting as follows:

"I saw the President drive into the grounds of the International Fair at 3 30 o'clock, stood in a tower from which I could see and hear the President give an outdoor address, and see him drive to the Temple of Music. At about four o'clock, as I sat in front of the Machinery Building, I watched an ambulance from the Emergency Hospital stop in front of the Temple of Music and saw a man carried out on a stretcher. Almost immediately I heard a report that the ambulance contained the President who had been shot, and I at once joined a riotous crowd that quickly gathered around a carriage which carried the assassin, intent on lynching him. I must confess that I, too, was carried away by the excitement and hate as I grasped the wheels of the carriage and struggled to get at the prisoner."

"Later I was shown the revolver with which the assailant did the shooting. It was an Iver Johnson 32 calibre, number 463344. One chamber was empty and the hammer was down."

"The President was nursed by women nurses assisted by four members of the Army Hospital Corps. The physicians in attendance made the mistake of being too optimistic. The abdominal operation was a success so far as the stomach was concerned, but at the autopsy the pancreas was found necrotic."

This Journal for October, 1901, had an editorial comment on medical publicity regarding the case

"We have cause for a deeper regret than others because the incident which at first promised to unfold to a wondering world the marvelous advances in surgical skill since Garfield's time has instead distinctly tended to lessen the respect of the public for our whole profession. It was not any lack of surgical skill that we have to deplore, for so far as we can see nothing was done or left undone that was not based on good judgment of all knowable conditions. It was not the issue of bulletins of too optimistic a tone, for it was a public duty at such a time to offer every possible encouragement. We give all praise to the operator who did all that human skill could do to save his distinguished patient. He would have received our felicitations had the outcome been happier as he now has our sympathy."

"To what, then, is due the grave public disapproval seen in every country newspaper? Though our colleagues did not show any lack of surgical skill, they exemplified one of the great evils of divided responsibility—they talked too much."

"This same tendency to talk too much has been evident far beyond the circle of the president's advisors. We have nothing but praise for the surgeons who testify publicly to the unquestioned surgical skill of the men under fire and urge us to assume till we have evidence of the contrary that this same skill was exercised in the case of our president. But what can we say of the men who if not distinguished themselves are at least the assistants of distinguished men, who from a distance of 500 or 1,000 miles offer criticisms in the public press? We suppose they hope to extend their local reputation, but we regret the fact that in our profession more than in any other are so many men whose education has not extended to the point of differentiating fame from notoriety."

MEDICAL PROGRESS

Glottic Spasm in the Adult—Spasm of the laryngeal muscles which, owing to the greater power of the adductors, results in a more or less complete closure of the glottis, is not of very frequent occurrence in the adult, but when it does exceptionally occur is most alarming to the patient and those about him. An attack begins usually with a sense of tickling in the throat followed by coughing and then closure of the glottis, impeding or wholly arresting inspiration though not interfering with expiration. Harold Barwell, writing on the treatment of this condition in *The Lancet* of July 3, says that, however alarming an attack may be, it is not dangerous except when due to tabes or thoracic aneurysm, or some other serious disease. Instant relief is often obtained by the inhalation of 5 minims of amyl nitrite or of a mixture of 10 minims of chloroform, 5 minims of ethyl iodide, and $\frac{1}{2}$ grain of menthol, these being enclosed in breakable glass capsules. A hot sponge applied over the larynx may also be of service. In the subacute attacks, in which the closure of the glottis is less complete but in which the distress may last several hours, the spasm may be broken by an emetic dose of ipecac—30 grains of the powdered root or 20 grains with half a grain of tartar emetic. In these persistent cases relief may also be given by a dose of 15 or 20 grains of chloral. In the preventive treatment between the attacks search should be made for any exciting cause, such as chronic pharyngitis or laryngitis, indigestion, overindulgence in tobacco or alcohol. In some patients a spasm is often brought on by drinking cold fluids. Little by way of prevention can be looked for from drugs, though a course of 10 grains of sodium bromide with 6 minims of tincture of nux vomica in some suitable menstrum, three times a day, may be helpful. In cases of aneurysm of the aorta or mediastinal tumor the attacks will recur almost inevitably despite attempts at prevention and hysterical cases usually show an obstinate tendency to recurrence. The tabetic attacks can usually be aborted by prompt inhalation of amyl nitrite.

Potassium Permanganate in Pneumonia—Herbert W. Nott reports in the *British Medical Journal* of July 17, 1926, a number of cases of pneumonia occurring in the practice of several physicians in which a rapid recovery followed rectal injections of potassium permanganate. The solution is made by adding 2 grains of pure permanganate to $1\frac{1}{2}$ pints of comfortably hot water, from 3 to 8 ounces being given by

enema every $2\frac{1}{2}$ to 4 hours. The injections should be given very slowly and should be repeated at short intervals if the bowel does not retain them long, or in case the treatment is begun after the disease is well established. Once the temperature reaches normal in adults and older children the injections are reduced to two a day for three days and then one a day for another three days. Most cases do not require hypnotics but cardiac tonics and stimulants may be called for, especially in septic cases. The changes seen in the clinical picture, under this treatment, are rapid and striking. "After the first or second injection the character of the cough alters from a harsh hawking bark to an easier and softer sound, the respirations become deeper and a little slower, with reduction in pleuritic pain in consequence. After the second or third injection the sticky expectoration becomes much looser and more easily raised. The grey or dusky type of cyanosis disappears in eighteen to thirty hours, being often replaced by a rosy complexion in children, whilst in adults the pneumonia facies gives way to an expression of ease. Sleeplessness, if it has been a predominant symptom, ceases. After the very first injection a child with advanced bronchopneumonia will fall soundly asleep, and can be kept sleeping by repeatedly giving small injections. Reduction of active and noisy delirium is noticed after a few injections, the patient becomes quiet and is more readily controlled after three or four doses have been well retained. But the most dramatic change of all is the sudden ceasing of the colored sputum. It is not uncommon to see a bright red sputum in the morning and to find white frothy expectoration in the evening of the same day."

Acrodynia and Its Cure—A. E. Vipond, writing in the *British Journal of Children's Diseases* for June, 1926, expresses disagreement with the prevalent opinion that acrodynia is a new disease or a resurrection of an old one. He thinks that cases have occurred with more or less regularity but without attracting particular notice until a keen observer like Bilderback came into the field of research. The symptoms and course of the disease, briefly summarized, are as follows. The initial symptoms are those of a nasal catarrh, but the child soon becomes more irritable than such a condition would justify. Following this is an erythematous or papulopustular eruption accompanied by cold sweating. Next observed is a pitiable condition of the extremities, the hands

and feet are cold and bluish-red in color due to the extremely sluggish circulation in the contracted arterioles and in the venules of the parts, the same condition appears on the tip of the nose, the edges of the ears, and the eyelids. There is intense pain in the affected parts, and a pseudoparalysis is noted in the lower extremities, so that the little sufferer is no longer able to stand or walk. The superficial nodes, especially in the axillae and groins, are enlarged. There is a rapid loss of weight, conjunctival irritation is marked, the reflexes are difficult to obtain, the urine is scanty. Untreated the disease lasts from 4 to 6 months. The age of the patients is between 8 and 18 months.

The disease is a toxemia of the central nervous system due to the presence of a specific microorganism, a small Gram-positive diplococcus, obtained by Vipond in cultures made from lymph removed under aseptic precautions from an enlarged inguinal node. A vaccine was made from this diplococcus and was employed with most satisfactory results in a number of cases. The initial dose is 1 cc containing 500,000,000 diplococci, and the vaccine is continued in increasing doses up to 3 to 5 cc. The author looks with confidence to a cure in about three weeks.

Treatment of Persistent Hiccup—C. F. T. East, writing in *The Lancet* of July 17, 1926, defines hiccup as due to a spasmodic contraction of the diaphragm causing an abrupt inspiration which is cut short by a sudden closure of the glottis. In the milder cases a cure can often be obtained by anything that takes the attention of the patient away from the expected hiccup, such as drinking from the farther side of the glass, holding the arms above the head and other "stunts." Pressure by the hand on the epigastrium or maintaining a posture with the knees drawn up and the thighs flexed on the abdomen may suffice in simple cases. In other cases pressure on the eyeballs or the supra-orbital nerves or a blister raised in the sensory area of the 3d and 4th cervical nerves at the root of the neck just above the clavicle, may arrest the spasms. Steady traction on the tongue for one or two minutes or a mustard plaster over the epigastrium may be useful. When basal pleurisy presumably causes the hiccups, tight strapping around the lower ribs, applied during expiration, has given excellent results. When the origin of the trouble is in the stomach carminatives are useful—a dram of spirit of chloroform, a teaspoonful of sal volatile in a little water, 5 minims of camphor in milk or on a lump of sugar, 5 to 10 minims of tincture of capsicum in water. In toxic conditions it may not be possible to combat the cause rapidly, and then we must treat the spasms

empirically. The following remedies have proved useful: Atropine hypodermically, gr 1/100 repeated in four hours if necessary; or tincture of belladonna, 10 minims every 4 hours. Benzyl benzoate in 20 per cent alcoholic solution, of which 20 minims in milk every two hours. Sedatives are sometimes necessary—hyoscine, chloral, the bromides, morphine, or Hoffmann's anodyne, a teaspoonful in iced water. An emetic may bring relief in an obstinate case. Nitroglycerin, 1/100 grain every 4 hours, or a sniff of amyl nitrite may arrest the spasm. Finally it may be necessary as a last resort to consider the injection of novocaine into the phrenic nerve at the root of the neck, both nerves must not be treated in this way on the same day. Among all these remedies some one should be found to give relief, and if one fails another must be tried.

Intraspinal Autoserotherapy in Epidemic Encephalitis—H. Pette relates his experience in Nonne's service for nervous maladies in the Hamburg-Eppendorf hospital. The number of patients submitted to this treatment was 23. It is not claimed that any revolutionary discovery has been made and while this particular form of treatment does not seem to have been applied before, convalescent serum from other patients has been tested as well as other kinds of serotherapy in intraspinal injection. From the fact that none of this series of patients succumbed to the disease it is evident that the treatment in question was not directed to the disease in its active phase, but rather to its troublesome sequelæ and especially the parkinsonian symptoms. The serum was taken from the patient's blood to the extent of 30 cc, tested for germ life, and inactivated, after which 10 cc was injected into the spinal canal. Despite the homogeneous source of the serum and the precautions taken, there seems to have been constantly present a considerable systemic reaction of general malaise, headache, and stiff neck with at times vomiting—in other words a distinct meningeal reaction. In a few cases only there was a febrile reaction to 39° C (103° F), although mostly the rise was only slight. The patients were taken as they came without any attempt at selection. In all 45 injections were given, averaging about 2 to a patient. The interval between two injections was long—from 3 to 6 weeks. The benefit was not apparent until after 6 or 7 days, and was then both subjective and objective. The author could see no evidence of anything specific in the treatment nor was there any remote effect on the duration of the disease. After a certain interval there was no further benefit to be seen, so that the transitory improvement could have been due in part to suggestion. In but one case was the result brilliant and the

gain in this patient has been maintained—*Muenchener medizinische Wochenschrift*, June 18, 1926

Isolated Gonorrheal Balanoposthitis—A Werner relates the case of a young man of 25 who appeared before him with an irreducible balanoposthitis. The first symptoms had appeared five days before and the irreducibility had persisted for two days. The use of the two-glass test of the urine excluded urethral discharge. The retention of much pus in the preputial sac was evident and some fever was present. Palpation and the microscope apparently excluded any kind of venereal ulcer, and the latter resource revealed the presence of gonococci. As attempts to treat the preputial sac without incision did not favorably affect the local symptoms or the fever, the author performed phimotomy with the result of a temporary fall of temperature. The fever reappeared, however, three days after the operation and was apparently due to double inguinal gonorrheal bubo. Five days of bed rest brought down the temperature, but an abscess formed in the region of the symphysis, the pus of which contained gonococci. Despite the successful evacuation and drainage the fever did not subside and later a specific tenovaginitis developed in the forearms, another abscess forming in the lower third of the extensor surface of the right forearm. Permanent deferescence followed incision and drainage of this abscess. The case is puzzling for the histological structure of the balanopreputial fold and adjacent membrane agrees fully with that of the skin and septic absorption from the latter, if at all intact, is not believed to occur. It absorption did not occur from the preputial sac the author suggests that it must have taken place through the paraurethral ducts and in sufficient virulence to infect both the blood and lymph streams—*Deutsche medizinische Wochenschrift*, June 18, 1926

Hypodermoclysis—Weller Van Hook, commenting on the recognized utility of the parenteral introduction of fluids into the body, cautions against the rapid injection of large quantities of fluid except in a great emergency. He protests against the violent disruption of the loose subcutaneous tissues by the sudden introduction of distending amounts of saline solution, for it serves no useful purpose to inject any fluid faster than it can be absorbed. He protests also against the thrusting of large needles, a millimeter or more in diameter, into the skin without first producing local anesthesia. All this is preliminary, he says, to the recommendation of a gentle and efficacious procedure which he has found most satisfactory in cases in which no great haste is called for, as when not more than two or three quarts

must be injected in the twenty-four hours. To a reservoir in which the fluid is kept warm by an electric light bulb, a tube is attached having a Y-joint at its lower extremity, from this extend two short tubes armed with gauge 18 hypodermic needles which are inserted, one under each breast, after previous anesthetization with novocaine. Each of these needles will deliver 50 cc per hour, or 1200 cc per day, the two therefore passing between 2 and 3 quarts of fluid every twenty-four hours—a fully sufficient quantity in most cases. The tube leaving the reservoir is interrupted by a drop-regulating mechanism, such as the procotolysis drip bulb—*Boston Medical and Surgical Journal*, July 29, 1926

Self-Stupefaction and Self-Destruction—This subject is discussed by E. Joël in the *Deutsche medizinische Wochenschrift*, of June 25, 1925. He first takes up narcotic addiction. Every act of stupefaction from drugs is an act of slow suicide. The author is not moralizing, but means simply that the flight from reality is the same, even if in one case it is temporary. The man who seeks temporary respite may one day choose to make it permanent. If a permanent addiction with constantly increasing dose and constantly diminishing euphoria results we may also speak of suicide. These persons may be likened in a way to ascetics and martyrs who also seek death. During the late war hundreds of thousands of human beings were tormented by anxiety, insomnia, actual pain from injuries, and extreme mental depression, and gradually learned for the first time of the existence and properties of numerous drugs, including actual poisons. The degree of knowledge thus acquired was such as to astonish the medical practitioner. Two examples are given. A man of 28, out of work, was the son of two suicides, the father having shot himself while the mother cut her wrist arteries and drank lysol. There were two other suicides in the mother's family. The patient himself had been a drunkard and had made two attempts at suicide and a brother had made six such attempts, and had also abused coffee and tobacco (50 cigarettes daily) while he resorted at times to veronal and luminal. A sister made two attempts at suicide with illuminating gas. A second patient had made two attempts at suicide with gas and was badly addicted to tobacco and coffee, with amblyopia *ex abusu*. His father is an alcoholic. Such cases are not exceptional but ordinary. The author recalls that Magnan regarded dipsomania as a suicide equivalent while Gaupp proved that addiction to alcohol, morphine, and cocaine often leads up to actual suicide.

Treatment of Hyperidrosis—H. Schmeidler refers to the extreme resistance to treatment of this affection. The phenomenon occurs under the most opposed conditions as in tuberculosis, obesity, pneumonia, and trichinosis. There are also localized forms, notably in the hands, feet, and axillæ, which may be complicated further by bromidrosis and by eczema. The view that these sweats are designed for the elimination of toxins and should not be suppressed has no foundation in fact, and while it is not desired to dry up the skin completely, arrest of the excess of perspiration always has salutary results. The best local application is formaldehyde which is a true specific in that it checks the excess of perspiration and neutralizes the irritating ammonium carbonate which forms in the decomposition of the fluid. The author does not mention the concentration used by him. If the skin is broken formaldehyde would cause smarting and he would substitute a mixture of powdered salicylic acid and starch. He recommends especially a remedy composed of several synergists, which contains alcohol, starch, zinc oxide, the ester of methyl salicylate, and formaldehyde, made up in ointment form. It has been found of value both by the author and Max Joseph and a case is cited in which it proved of inestimable service in drying up the sweating hands of a dentist who had gone unrelieved for many years.—*Deutsche medizinische Wochenschrift*, June 18, 1926

Mercurial Poisoning from Dental Fillings—F. Flury refers to an article recently published by a well known chemist in which he relates the experience of himself and collaborators in a form of intoxication from exposure to mercury fumes in ordinary laboratory activities. Incidentally he touches on the possibility of poisoning from fillings of mercury amalgam. The subject is an ancient one, going back a century or more. The first metal to be accused in this respect was, however, silver in the form of amalgam (in 1846), although study of the cases makes it probable that mercury was the metal at fault at least in some of the cases. In alleged poisoning from copper amalgam, published many years afterwards, mercury is recognizable as the toxic substance. Doubtless in these cases we must reckon on the presence of an idiosyncrasy to mercury. Stock, the chemist to whom Flury refers, points out that mercury amalgam may cause an insidious form of poisoning, which is readily overlooked. The symptoms show much variability, the majority

being nervous and mental, as prostration, irritability, headache, vertigo, etc. Others affect the digestive tract, as stomatitis, anorexia, and diarrhea, and still others the respiratory tract, as nasal catarrh. Stock's paper roused great interest among dentists and the general public, for literally millions of the people carry these fillings in their mouths. That any considerable number of these have ever been poisoned by the mercury seems incredible except through two possibilities, namely personal idiosyncrasy to mercury and the use of an improper amalgam. Many dentists assert that such a case has never come before them even as suspicious. The mechanism would doubtless involve the volatilization of the metal of the filling and subsequent inhalation. Stock promises to write a second paper on the subject with further data.—*Muenchner medizinische Wochenschrift*, June 18, 1926

Absolute or Relative Count in the Valuation of the Leucocyte Blood Picture—Professor Victor Schilling sums up a serial article, concluded in the *Deutsche medizinische Wochenschrift*, of June 18, 1926, as follows. Moschkowski in his critique blames certain defects of the relative determination of the leucocytes but omits to mention that the deliberate rejection of absolute curves for practical purposes promotes the valuation of the blood picture for diagnosis which has been made possible in wide circles. He gives an absolute method of his own which seems to us quite unfeasible for the demands of practice and recommends this method in pointing out certain alleged defects of our own technique (errors in the nuclear index employed in various scales), which do not exist at all or exist as a result of apparently scientific heresy (monocytosis of the protozoan diseases), which show themselves according to absolute figures as correct. Finally Moschkowski omits, on his part, to demonstrate practical results with his new methods, which are equal to those obtained by the Schilling method by Dornedden, Dungal and a dozen others. We reject the critique of Moschkowski directed against the relative leucocyte method as entirely incorrect. The precision of Moschkowski's labors can therefore not delude us as to their impracticability and only partial justification. Every objective critique must recognize the superior advantages of the relative count even in admitting the existence of sources of error, its greater constancy, its clinical lucidity and the simplicity of the demonstration.

NEWS NOTES

THE SIXTH DISTRICT BRANCH

The first of the District Branches to hold a meeting this fall was the Sixth, whose meeting was held on September 21st in the Country Club at Owego, with the president, Dr Wilber G Fish, of Ithaca, presiding, and the Secretary, Dr Hubert B Marvin, of Binghamton, recording

The attendance was 59 members out of a total membership of 446 in the ten component county societies. The percentage of attendance was 13, which is large. In addition 27 physicians were present as guests. The Sixth District Branch has always been noted for its large attendance.

The members at the meeting were the guests of the Tioga County Medical Society of which Dr E S Peck of Owego is president. The County Society provided a buffet lunch at noon, and entertainment and afternoon tea for the ladies. The day was perfect, and the broad verandas of the club house afforded the opportunity for visitations among the doctors.

The program was practical and the speakers held the attention of the audience. Emphasis was placed on public health, and four counties presented reports of their practice of civic medicine along original lines.

The first number on the program was a report on "The antidiphtheritic campaign in Chemung County," by Dr Reeve B Howland, Health Officer of Elmira. He and Dr John A Conway, District State Health Officer, described the immunization of nearly 2,000 school children in Elmira and some of the surrounding districts, and contrasted the low rate of incidence of diphtheria in the immunized communities with that in the places in which immunization had not been done. They also told of some rare cases of opposition by health officers and school medical inspectors.

An animated discussion followed the paper, in which the physicians who spoke praised the work of the health officers. While few doctors reported having done the immunizations in their private practice, the consensus of opinion was that they should be done to all the children in the families in the care of a physician.

On motion of Dr Howland, the Sixth District Branch unanimously approved the antidiphtheria campaign conducted by the Medical Society of the State of New York, and recommended that the County Medical Societies and the family physicians take part in doing the immunizations, in both public and private practice.

The reconstruction work on polio cases done in Tompkins County was described by Dr C D Reed, Orthopedist of the State Department of Health. The cases of Tompkins County received care in the Reconstruction Home in Ithaca. This is a striking example of the practice of civic medicine by a lay organization directed by medical men.

"The Tioga County experiment in pre-natal care" was described by Dr Guy A Carpenter of Waverly. The work was begun in January, 1925, when two nurses were sent to Tioga County by the State Department of Health. The County Medical Society had considered the matter in December, 1924, and had agreed to direct the nurses' work through a committee composed of physicians. The nurses are paid by the State Department of Health, but their work is directed entirely by the doctors' committee. They do pre-natal and obstetrical work under the direction of physicians. They visit pregnant women, take their blood pressures and analyze their urines, and advise them regarding the danger signs of which they may expect. They also assist the doctors in the confinements and visit the mothers and babies afterward.

In 1925, Tioga County had 375 obstetrical cases of which 245 were seen by the nurses. Each case was visited 15 times on an average.

The doctors of the county were almost unanimous in favor of the public health nurses. There was no question regarding the great benefit to the mothers and babies. The point was made that from a selfish standpoint doctors favored the work because it relieved them of much care and responsibility for the cases.

The work also reacted on both the people and the doctors. The people now realize the importance of pre-natal care, see the safety and comfort of hygienic deliveries, and seek the help of the doctors more than ever before.

The future of the demonstration was also discussed, and the point was raised whether or not it was right to accept help from the State Department of Health and from the National Government through the Sheppard-Towner funds. The issue of State Medicine was also raised but was not emphasized in view of the demonstrated popularity of the work with the physicians, the mothers and the community. The opinion of the speakers seemed to be that the work should be continued by the county government, and would be if the people and the doctor so demand.

The discussion of the pre-natal work in Tioga County was snappy and broad and covered every phase of the work within a half hour. All the speakers agreed that the doctors of Tioga County had shown how they could successfully direct and control public health work which had usually been done by lay organizations.

The Steuben County experiment in Breast Feeding, was described in a paper by Dr Charles R Wakeman, District State Health Officer, which was read and amplified by Dr John A Conway. A preliminary report of this work is contained in an article by Dr Wakeman, entitled "Hornell Breast Feeding Demonstration," printed on page 831 of the July, 1925, issue of this Journal. This work consisted in following up the babies during their first year of life. The results of the work were that a very unusually large proportion of mothers nursed their babies, and that while the incidence of diarrhea and death among the breast fed babies was practically nothing, there were ten deaths among bottle-fed babies in a single outbreak.

The breast feeding demonstration was another example of public health work originated and demonstrated by doctors.

"The Educational Program for the Control of Cancer" was described by Dr La Rue Colegrove of Elmira.

The most striking number on the program was that on "Pre-natal care and Child Welfare in Soviet Russia," by Dr Stuart B Blakely of Binghamton. Dr Blakely had gone to Russia in 1925 in order to study the treatment of eclampsia as exemplified by Dr Stroganoff

of Moscow, who has had an extensive experience in that disease. Dr Stroganoff has a mortality rate of only two or three per cent which is much lower than anywhere else. His method consists in non-operation and non-interference with the pregnancy, the enforcement of absolute quiet and rest and the administration of morphine and chloral as sedatives. Dr Blakely also discussed the baby-saving work in Soviet Russia, and showed lantern slides of an extensive series of educational posters of which millions of copies were distributed in order to teach the ignorant peasants how to care for their babies. The posters were works of art, and exemplified their points with far more force and directness than similar ones in America. They were bold and were unrestrained by social customs, as in America. One cartoon, for example, showed a baby in its chair sucking a milk bottle while a cow stretches out her neck and says with a quizzical look "Why do you drink my milk? Don't your mother give you her own breast?"

Another poster shows the views of the female organs of generation, and has the caption "The emptied uterus is an open wound which may take up blood poisoning."

Dr Blakely plans to send the posters for reproduction in this Journal.

The officers of the Sixth District Branch are to be congratulated on arranging a public health program that excited the interest and admiration of the members. The County Medical Societies are also to be congratulated for having carried on public health work and civic activities which received the cooperation of general practitioners of medicine.

THE THIRD DISTRICT BRANCH

The Twentieth Annual meeting of the Third District Branch of the Medical Society of the State of New York was held on September 25 in Albany, in the Harmanus Bleeker Library, two blocks west of the Capitol. The President, Dr Charles P McCabe, of Greenville, presided, and the Secretary, Dr Clarke G Rossman, of Hudson, recorded.

There were 50 members of the District Branch present out of a total membership of 529—a percentage of 9 attending the meeting. The attendance of members by counties was as follows:

Albany	36
Schoharie	5
Columbia	3
Greene	2
Rensselaer	2
Ulster	2
Sullivan	0

In addition there were 20 guests present, including six members of the official staff of the Medical Society of the State of New York.

A morning session was begun at 10 o'clock. The members were guests of the Medical Society of the County of Albany at a luncheon in the Fort Orange Club. A business session was held at 2 o'clock and was followed by a general session which adjourned at 4 10 o'clock.

The ladies were entertained at luncheon at the Albany Country Club by the wives of the members of the Albany County Medical Society.

Many of the members remained in order to attend the annual clambake of the Albany County Medical Society at McKown's Grove.

At the business session, the following officers were elected to take office at the close of the Annual Meeting of the State Society.

President, Dr E A Vander Veer, Albany
First Vice President, Dr Herbert A Odell,
Sharon Springs

Second Vice President, Dr Clark A Rossman,
Hudson

Secretary, Dr William M Rapp, Catskill
Treasurer, Dr Ernest E Billings, Kingston

The following program was carried out
Address of Welcome, by William P Howard
M D, President, Albany County Medical Society
President's Address, by Charles P McCabe,
M D, resident of the Third District Branch

Paper, "Post-Graduate Education," by Henry
J Noerling, M D, President of Columbia County
Medical Society

Address, "Periodic Health Examinations," by
Haven Emerson, M D, illustrated with the moving-picture film on "How to Make an Examination"

Address, "Medical Legislation," by Henry L
K. Shaw, M D, Chairman of the Legislative
Committee of the Medical Society of the State
of New York

Address, "The Accomplishments of the Medical
Society of the State of New York," by Dr
George M Fisher, President

Address, "The Importance of the County
Medical Society," by Dr James E Sadlier, President-elect,
Medical Society of the State of New York

Address, "The Business Organization of the
State Medical Society," by Dr Daniel S Dougherty,
Secretary

Address, "The Function of the District
Branch," by Dr J S Lawrence, Executive Officer,
Medical Society of the State of New York

Address, "The New York State Journal of
Medicine," by Dr O S Wightman, Editor-in-Chief

Address, "New Problems in the Private Practice
of Medicine," by Dr William A Howe, New
York State Department of Education

All the subjects on the program concerned the
practice of public health and civic medicine, and
dealt with the doctor's public duties in contrast
with his private duties in treating sick individuals

Dr Wightman, speaking of news, said that
several complaints had already been referred to
the Grievance Committee, and that two convictions
for malpractice under the amended law had
already been secured by the Attorney General,
showing that the law is already in operation

Dr Fisher, after reviewing what the State
Medical Society had done in the past, referred to
the demand of the public for more medical
knowledge which must come from the doctors.
'No longer must the doctors remain passive,'
said he, "they must lead in health education"

Dr Sadlier said that the County Medical

Society was the foundation on which the medical
profession rests. He spoke of the lack of co-
ordination among doctors in the past, and referred
to epidemics which ran on for months because the
doctors did not unite in their suppression. In
contrast with the former discord, he described
the installation of a filter system for the water of
the city of Poughkeepsie, through the efforts of a
committee from the County Medical Society. This
is the kind of work which Dr Sadlier considered
should be done by County Medical
Societies

Dr Sadlier also referred to the increased
efficiency of medical service to rural communities,
and he considered that the migration of doctors
from rural places to the larger centers of population
had its recompenses to the people in the
greater skill coming to the doctors as the result of
their closer association. He also cited as evidence
of better medical service the growth of hospital
beds in Dutchess and Putnam counties from 90
in 1912, to 600 in 1926 and all of them now filled

Dr Sadlier, in closing, advocated an active
committee on public health in every county, which
should promote the practice of public health
measures by physicians, such as the immunization
of their child patients with toxin-antitoxin as a
preventive against diphtheria

The function of the District Branch was dis-
cussed by Dr Lawrence and others. It was the
consensus of opinion of the speakers that it was
not the function of the District Branch to confine
its activities to holding a meeting once a year
with a scientific program modelled after the sec-
tion meetings of the State Society. The District
Branch should be the stimulator of its component
county societies, and its officers and committees
should be prepared to help them. The program of
the meetings of the District Branches might well
include a discussion of the problems of the county
societies

Many members commented, both publicly and
privately, on Dr Noerling's address on "Post
Graduate Education," and the meeting voted to
request Dr Noerling to arrange its publication in
the State Journal

A pleasing feature of the meeting was an in-
formal talk by Dr F C Curtis of Albany, a
former president and secretary of the State Medi-
cal Society. Dr Curtis said that he had joined
the Albany County Medical Society in 1872, and
ever since he had made it a point to attend its
meetings regularly. He considered the County
Society the most important of all medical or-
ganizations, for it was composed of physicians
who make the first contact with the people. They
come into close contact with all that enters into
living. They gain new vitality as they appropri-
ate the ideas of their brother doctors, all of whom
work under the same conditions

REGISTRATION OF PHYSICIANS

By AUGUSTUS S DOWNING, ASSISTANT COMMISSIONER OF EDUCATION

There were approximately 17,500 registration cards mailed on the 8th of September. Effort was made to reach every practicing physician in the State but any physician who was overlooked may obtain a card by writing this office. Up to September 22, something over 5,000 applications have been received. They are coming in by every mail and quite rapidly.

Some mistakes, omissions, and questions have come up. The great majority of the cards are properly filled out and raise no question. There are, however, a few questions that have come up to which the attention of the profession might be called.

(1) Many of the practitioners who began practice prior to the time it was necessary to secure a license from this Department wonder, quite naturally, how they shall fill in the line calling for number and date of license. The answer is that such a practitioner should write in this space the name of the institution from which he graduated and the year. This we have found is the information we would like these practitioners to furnish us. There is another space on the card in which the applicant is to write the name of the county in which his license was originally recorded. Knowing this county and the college from which he graduated and the date, we can check the records of the older practitioners of this kind.

(2) If a practitioner has his residence in one place and his office in another, even if they are in two different localities, it is not necessary for him to file two applications for registration, that is to say one from each address. Every physician is required to file but one application, for the reason that the certificate issued as a result of such application validates his practice for the year for which it is issued in any part of the state.

(3) The law requires that the application be made under oath and that the fee of \$2.00 shall accompany the application. Quite a number of applications have come in without the oath and more without the fee. If every applicant is

careful to make the affidavit and inclose the fee, it will help the Department and expedite matters considerably.

(4) A number of physicians who are residing for a time outside of the State of New York have inquired whether they lose the right to practice in this State if they do not register. Since no physician may practice in the State of New York who has not registered with this Department, these out-state physicians do lose temporarily the right to practice within the State, but by reason of the fact that they hold New York State licenses, they may resume practice in the State of New York at any time by registering with this Department.

(5) Some physicians say they are not practicing and do not wish to register, but they do wish to be known among the practicing physicians of the State. The list of physicians which this Department will publish after the registration will be a list only of those who have registered, and the list will not contain the names of those who did not register because they were not obliged to do so.

(6) Physicians should bear in mind that it is in violation of the law to practice medicine without registering with this Department. The Commission of a single act may constitute the practice of medicine, and every physician who expects to be in the State of New York for even so little as one day during the year 1927 and who may on that one day do something which constitutes the practice of medicine, should make application for registration.

(7) All physicians should send in their application cards immediately. All of these application cards must be checked and the list of practicing physicians prepared. The proper compilation of such a list and its printing is no small task, and unless the Department receives the fullest cooperation from the physicians of the State, the publication of the list may be delayed and the advantages of an early distribution of this list among the profession be impaired.

OTSEGO COUNTY MEDICAL SOCIETY

A meeting of the Otsego County Medical Society was held on September 14, with seventeen members present, out of a total membership of forty-two. A business session was held at which the establishment of a pathological laboratory in Oneonta was discussed. Steps were taken to bring the matter before the proper authorities.

Dr Samuel Tirman, of Brooklyn, gave an

interesting clinical lecture on the common forms of heart diseases. Several cases were presented for examination.

The consensus of opinion of the members was that the county society should have another series of lectures on pediatrics next spring if they can be arranged.

Dr Herbert C Hageman was elected to membership.

THE DAILY PRESS

IS NOISE HARMFUL TO HEALTH

A health officer is likely to say it is not, until he is kept awake all night by the honking of automobile horns. A person does not have to be "nervous" to be injured by a strident noise—the noise itself is a sufficient cause of mental suffering, which is as real and intense as that of a tooth-ache or appendicitis.

This topic is editorially discussed in the New York *Herald-Tribune* of September 7.

"The ordinary horn or klaxon used in moderation assaults the ear sufficiently. The hubbub is scarcely less if the siren is barred, as in Paris, and the tooting is limited to the old-fashioned bulb horns. There is sufficient wear and tear on the nerves from these piercing notes. The Paris Prefect of Police has just appointed a committee to select an auto horn less shrill than the city has endured, he has decreed, moreover, that promiscuous honking must cease. Many American visitors have found the incessant tooting of

the Paris taxicabs as irritating as the varied noise-making devices of automobiles in New York. The psychology of this type of necessary disturbance has not been thoroughly explored."

"The state motor vehicle law prescribes 'a suitable and adequate horn or other device for signaling, which horn or device shall produce a sound sufficiently loud to serve as a danger warning, but shall not be used other than as a reasonable warning nor be unnecessarily loud and harsh.' It appears, therefore, to be within police power to keep the racket in tolerable bounds. When the uniform motor legislation so much desired is worked out it should include, perhaps, for all cities the requirement of a standard warning signal distinct enough to arrest attention without setting every nerve on edge. Meanwhile, the collaring of some of the most gratuitous noise-makers might be helpful."

THE IMMORTALITY OF THE BODY

In what does immortality of the body consist? It does not lie in a persistent activity of the majority of its individual particles, for life is dependent upon a continued oxidation and replacement of their matter, although some parts, such as the enamel of the teeth, undergo little or no change after they are formed. It is not in the continued identity of the cells, for new ones are formed and old ones discarded every day, especially from the surface of the skin. Immortality consists in a continued identity of living characteristics, even when none of the original particles or cells remain.

The theory of cell division requires the assumption of a continuous stream of life reaching backward through an interminable line of dividing cells until the original primordial cell is reached. It is easy to visualize the life of a cell continuing in each of the two into which it divides, but when a new human individual is created, one cell only is chosen as the transmitter of immortal life and all the other cells of the parent body die and decay.

The New York *Sun* of September 15 quotes Dr. Raymond Pearl, Director of the Institute of Biological Research of Johns Hopkins University:

"Nothing like death is inevitable in the cell itself."

The cell when placed separately under such

conditions as to supply appropriate food in the right amount and to remove promptly the deleterious products of metabolism, or chemical changes, can probably live forever."

"This assertion is based on the successful cultivation of tissues from man's body, and the bodies of other animals, achieved during the last few years. Dr. Pearl says that the experimental culture of cells and tissues has now covered virtually all the essential elements of the metazoan body, including even some of the most highly differentiated of those tissues, nerve cells, muscle cells, heart muscle cells, spleen cells, connective tissue cells, epithelial cells from various locations in the body, kidney cells and others have all been successfully cultivated *in vitro*, or in special nutrient mediums."

Particularly striking is the culture work of Carrel and Ebeling. These great scientists, by transferring the culture at frequent intervals into fresh nutrient medium, have kept alive for more than fourteen years, and in perfectly normal and healthy condition, a culture of tissue from the heart of a chick embryo. There is every reason to suppose that by a continuation of the same technic, the culture can be kept alive indefinitely. Although we die, our cells have the capacity to live forever. Not even senescence, or old age, is a necessary concomitant of cellular life."

"A fundamental reason that higher multi-cellular animals do not live forever is the differentiation and specialization of function of the cells and tissues of the body as a whole. In the body, any part is dependent for the necessities of its existence, as for example nutritive material, upon other parts. It is, there-

fore, the mutually dependent aggregate of cells and tissues that brings about death, and not any inherent or inevitable mortal process in the individual cells themselves."

These speculations may not be especially practical, but they illustrate ways in which physicians may discuss a popular topic

EXTRA-TERRITORIALITY

Those who uphold the insistence of Europeans on maintaining their own government and courts in foreign lands will find its justification on hygienic grounds in an editorial from the *New York Herald-Tribune* of August 13th describing conditions in Shanghai, where a thousand Chinese are dying daily of cholera in the old city, and none in the new. The editorial says:

"To understand the significance of these figures and their bearing upon the question of foreign concessions in China it is necessary to recall the origin of the Shanghai 'settlement.' There was a huge Chinese city on the Woosung long before the foreigner came. When, in 1843, the port was opened to foreign trade, the foreigners found its population living under conditions which would have meant early death for Europeans. They asked for an allotment of land where they could build houses and streets after their own kind, and the Chinese assigned the swamplands along the river bank below the city. The worth-

less marsh was considered quite good enough for the foreigner.

"The foreigners accepted the land assigned, and upon it during the succeeding fourscore years they have built a magnificent modern city, whose broad avenues and towering buildings quite overshadow the old Chinese metropolis. The Chinese themselves have not been slow to seek the advantages of the foreign settlement, and they have moved into it by thousands, so that to-day about 90 per cent of its inhabitants are Chinese.

"During all of these years, despite the influx of Chinese, the foreigners have kept the municipal administration in their own hands. Sanitation, roads and streets and police protection have been rigorously kept up to foreign standards. It is only necessary to look at the surrounding towns, at the native city of Shanghai itself, and the conditions which prevail there under Chinese administration, to see why the foreigners living in the settlement insist upon retaining their control."

LIGHT MEALS

There are fashions in eating as in most other customs. Lunches like clothing are now scanty and light.

The *New York Herald-Tribune* of September 10 contains an account of an investigation made by a representative of a chain of drug stores regarding what folks eat for lunch. The article says:

"The average mid-day meal for persons of sedentary proclivities has become so lightsome that it is almost frivolous. A cup of coffee, a sandwich and pie is the masculine version of the affair, while chocolate malted milk and a sandwich is the staple of the channel-swimming sex.

"The decrease in the sale of patent medicines is undoubtedly due to the fact that people are eating less," Mr Griffiths continued. "In the country, where the people still eat heavily, panaceas and cure-alls still have a large sale. It is only in the cities where people are eating less that the patent medicine trade is on the decline.

"Then there is the subject of coffee. Six

years ago hardly any drug stores sold coffee over the counter," Mr Griffiths says. "But now there probably are more than 1,000 drug stores in town where coffee and sandwiches may be had. The most popular sandwiches are ham, cheese and chicken, in the order named.

"Prohibition, everybody says, has nothing to do with the lighter lunch movement. People are just eating less, that's all, and as a result they tackle the afternoon's work with less distaste. And besides, they can always even things up at dinner."

Temperance in eating undoubtedly is a considerable factor in the raised standard of general healthfulness of a community. A "skinny" boy or girl is a rarity, while an excess of fat is coming to be considered a humiliation. Folks generally are willing to diet themselves for the sake of health. If their undirected frugality gives evident results in nutrition, much more dieting directed by intelligent knowledge will bring about a higher standard of physical strength and vigor, and mental alertness.

BOOKS RECEIVED

Acknowledgment of all books received will be made in this column and this will be deemed by us a full equivalent to those sending them. A selection from this column will be made for review as dictated by their merits, or in the interests of our readers.

HYDROGEN ION CONCENTRATION OF THE BLOOD IN HEALTH AND DISEASE. By J HAROLD AUSTIN and GLENN E. CULLEN Octavo of 75 pages Baltimore, Williams and Wilkins Company, 1926 Cloth, \$2.00 (Medicine Monographs, Vol. VIII)

PERNICIOUS ANEMIA By FRANK A. EVANS M.D 12mo of 178 pages Baltimore, Williams and Wilkins Company, 1926 Cloth, \$2.50

ROENTGEN INTERPRETATION A Manual for Students and Practitioners By GEORGE W HOLMES, M.D., and HOWARD E. RUGGLES, M.D Third edition, revised. Octavo of 326 pages with 226 illustrations. Philadelphia and New York, Lea and Febiger, 1926 Cloth, \$5.00

EDGAR'S PRACTICE OF OBSTETRICS FOR STUDENTS AND PRACTITIONERS OF MEDICINE. By J CLIFTON EDGAR. Revised by NORRIS W VAUX Sixth Edition. Octavo of 779 pages with 684 illustrations Philadelphia, P Blakiston's Son and Company, 1926 Cloth, \$8.00

HAY FEVER AND ASTHMA A Practical Handbook for Hay Fever and Asthma Patients By RAY M BALYEAT, A.M, M.D 12mo of 198 pages with 27 illustrations. Philadelphia, F A. Davis Company, 1926 Cloth, \$2.00

AURICULAR FIBRILLATION By J G EMANUEL, B.Sc., M.D, F.R.C.P The Ingleby Lectures, delivered at the University of Birmingham, May 6th and May 13th, 1925 Octavo of 31 pages. Birmingham, Cornish Brothers, Ltd., 1926 Cloth, £0-3-6

THE PEAKS OF MEDICAL HISTORY An Outline of the Evolution of Medicine for the Use of Medical Students and Practitioners By CHARLES L. DANA, A.M, M.D, LL.D Octavo of 105 pages, with illustrations New York, Paul B Hoeber, Inc., 1926 Cloth, \$3.00

MESENTERIC VASCULAR OCCLUSION Supplemented by an Appendix of 76 Original Cases By A. J COCKINIS, M.B, B.S, F.R.C.S Octavo of 159 pages Eng New York, William Wood and Company, 1926. Cloth, \$4.00

CARBOHYDRATE METABOLISM AND INSULIN By JOHN JAMES RICKARD MACLEOD, F.R.S, M.B Octavo of 357 pages with illustrations. London and New York, Longmans, Green and Company, 1926 Cloth, \$6.00. (Monographs on Physiology)

THE SECRETION OF THE URINE. By ARTHUR R. CUSHNY, M.A., M.D Second edition Octavo of 288 pages with diagrams London and New York, Longmans, Green and Company, 1926 Cloth, \$5.50 (Monographs on Physiology)

BAINBRIDGE AND MENZIES ESSENTIALS OF PHYSIOLOGY Fifth edition, edited and revised by C. LOVATT EVANS, D.Sc., M.R.C.S Octavo of 508 pages with illustrations London and New York, Longmans, Green and Company, 1925 Cloth, \$5.00

BIRTH CONTROL AND THE STATE A Plea and a Forecast By C P BLACKER, M.C., M.A. 16mo of 87 pages New York, E. P Dutton and Company, 1926 Cloth, \$1.00

BRAINS OF RATS AND MEN A Survey of the Origin and Biological Significance of the Cerebral Cortex. By C. JUDSON HERRICK 12mo of 382 pages with illustrations Chicago, The University of Chicago Press, 1926 Cloth, \$3.00

FUNDAMENTALS OF DERMATOLOGY By ALFRED SCHALKER, M.D 12mo of 239 pages, with illustrations. Philadelphia and New York, Lea and Febiger, 1926 Cloth, \$3.00

THE TREATMENT OF FRACTURES WITH NOTES UPON A FEW COMMON DISLOCATIONS By CHARLES LOCKE SCUDDER, A.B, Ph.B, M.D Tenth edition, revised Octavo of 1240 pages, with 2027 illustrations. Philadelphia and London, W B Saunders Company, 1926 Cloth, \$12.00

SURGICAL ANATOMY OF THE HUMAN BODY By JOHN B DEEVER, M.D, Sc.D., LL.D, F.A.C.S Second edition in three volumes, thoroughly revised and rearranged Volume I Scalp, Cranium, Brain, Face, Mouth, Throat, Organs, of Special Senses Quarto of 551 pages with illustrations Philadelphia, P Blakiston's Son and Company, 1926 Full fabricoid, \$36.00, payable \$12.00 upon receipt of each volume.

RECENT ADVANCES IN OBSTETRICS AND GYNÆCOLOGY By ALECK W BOURNE, B.A., M.B., B.Ch.(Camb), F.R.C.S (Eng) 12mo of 344 pages, with illustrations Philadelphia, P Blakiston's Son and Company, 1926 Cloth, \$3.50

SURGICAL CLINICS OF NORTH AMERICA Vol 6, No 3 June, 1926 (Lahey Clinic Number) Published every other month by the W B Saunders Company, Philadelphia and London. Per Clinic Year (6 issues) Cloth, \$16.00 net, paper, \$12.00 net.

MEDICAL CLINICS OF NORTH AMERICA. Vol. 10, No 1 July, 1926 (Philadelphia Number) Published every other month by the W P Saunders Company, Philadelphia and London. Per Clinic Year (6 issues) Cloth, \$16.00 net, paper, \$12.00 net.

CLINICAL PEDIATRICS By JOHN LOVETT MORSE, A.M, M.D Octavo of 848 pages, illustrated. Philadelphia and London, W B Saunders Company, 1926 Cloth, \$9.00

ELEMENTS OF PATHOLOGY By ALLER G ELLIS, M.Sc M.D Octavo of 544 pages, with 95 illustrations Philadelphia, P Blakiston's Son and Company, 1926 Cloth, \$5.00

PSYCHOLOGICAL MEDICINE. A Manual on Mental Diseases for Practitioners and Students By SIR MAURICE CRAIG, M.A., M.D, and THOMAS BEATON, M.D Fourth edition Octavo of 437 pages, with 25 plates Philadelphia, P Blakiston's Son and Company, 1926 Cloth, \$6.00

BOOK REVIEWS

HYGIENE OF SEX By MAX VON GRUBER. Authorized English translation. 12mo of 169 pages. Baltimore, Williams and Wilkins Company, 1926. Cloth, \$1.50

We have always fought shy of semi-popular books and sex and when we undertook to review this one it was no exception to the rule. Carrying it with other volumes under our arm we met with one of the solid men of the profession. He informed us he had read "Hygiene of Sex" and that he had found it one of the 'best of its kind'.

We find it sane, non-sensational, true and tending towards common sense. It has chapters devoted to "Fertilization," "Heredity and Breeding," "The Organs of Sex," "The Sexual Instinct and the Assumed Necessity of Coitus for Health," "The Limitation of Conception," "Aberrations of the Sexual Instinct," "Venereal Diseases and Their Prevention," "Marriage or Free Love."

The jacket tells us that 300,000 copies have been sold abroad.

To those interested in this subject this small volume of 169 pages offers the best of its type to the lay-reader.

T W

CHEMISTRY AND RECENT PROGRESS IN MEDICINE. By JULIUS STIEGLITZ. Octavo of 62 pages. Baltimore, Williams and Wilkins Company, 1926. (The Johns Hopkins University School of Medicine, The Charles E. Dohme Memorial Lectureship, Second Course, 1924.)

In 1916, Mrs. Chas. E. Dohme of Baltimore founded a lectureship in chemistry at Johns Hopkins in memory of her deceased husband, a well-known chemist. Through her generosity, the public has benefited by an admirable series of lectures linking chemistry and medicine. This volume comprises the lectures delivered by Prof. Stieglitz in May, 1923.

He first discusses the uses of drugs foreign to the body such as ethylene gas, tryparsamide and the anti-septic dyes, showing the progress made and the great possibilities of the future. Next he discusses the isolation and use of internal secretions, particularly insulin, pituitary and ovarian hormones, the vitamins and recent progress in the purification and improvement of antisera. He next gives an account of Howland and Marriott's work on calcium metabolism, Henderson's work on carbon dioxide and concludes with an extended discussion of the present theory of the fundamental principles of oxidation.

Some of the above is familiar to most of us but the theory of oxidation is new and important as it does much to explain the basic processes of cell life. These lectures are not too technical, are interesting and should be read by many, but especially by the laity, for the striking picture of what organized chemical research has contributed in America to medical progress.

E. B. SMITH

ARCHIVES OF THE ANDREW TODD MCCLINTOCK MEMORIAL FOUNDATION FOR THE STUDY OF DISEASES OF THE ALIMENTARY CANAL. Volume 1. Pleomorphism in Bacterial Protoplasm. A study in Psittacosis. By ANDREW TODD MCCLINTOCK, M.D. Octavo of 240 pages. Privately printed, 1925.

This is a most interesting record of research in an epidemic of psittacosis occurring in Wilkes-Barre, Pa., in 1917. The epidemic is traced from its source in a group of parrots on sale in that city through a considerable number of human victims. After the epidemic subsided, the author conducted a remarkable and exhaustive

series of experiments with the causative organism, a pleomorphic bacillus. His findings are most interesting to the bacteriologist, but just as interesting is the picture one gains of the author. One senses that he had a rare and remarkable mind and regrets that he could not live to enjoy the brilliant future that would inevitably have been his.

E. B. SMITH

A TEXTBOOK OF PHYSIOLOGY By WILLIAM D. ZOETHOUT, Ph.D., Professor of Physiology in the Chicago College of Dental Surgery (Loyola University). Second edition. The C. V. Mosby Co., St. Louis, Mo., 1925. Price, \$4.50.

In the preface the author states that his book is "intended to fill the gaps between the larger texts [on physiology] of which there are many in the field, and those offering a briefer course." In preparing such a volume the author assumed no easy task but a perusal of his book shows he has acquitted himself well. After a preliminary discussion of the physics and chemistry of the cell the author considers the major phenomena of general physiology, such as muscle-nerve reactions, the circulation and coagulation of blood, digestion, respiration, special sense organs, etc. The author has purposely avoided voluminous discussion of involved and obscure theories concerning topics physiological but rather has aimed to make his book a practical one. With the latter purpose in mind considerable space has been devoted to such timely subjects as physical exercise, mental work, nutrition and fatigue.

The section on the physiology of vision is exceptionally fine.

FRANK E. MALLON

ANESTHESIA By JAMES TAYLOR GWATHMEY, M.D. With Collaborators on Special Subjects. Second revised edition. Octavo of 799 pages, with illustrations. New York and London, The Macmillan Company, 1925. Cloth, \$7.50.

As compared with earlier editions of the same book and the other texts on anesthesia, this revised edition shows the enlargement of the field of anesthetic agents. We find the usual routine chapters on the history, physiology and action of the various agents, all brought up to date and carefully described.

The section on local and spinal anesthesia is an additional volume in itself, and gives the reader all this information, which usually has to be looked for in a separate book, and adds greatly to its value as a reference. The chapters on the practical application of anesthesia are clearly written, and should be useful both to the beginner and to the expert. The selection of anesthetic, the technique for special operations and the treatment before and after operation, practical problems in the life of the medical man, are made very clear.

Geo. W. TONG.

PARENTHOOD AND THE NEWER PSYCHOLOGY Being the Application of Old Principles in a New Guise to the Problems of Parents with Their Children. By FRANK HOWARD RICHARDSON, A.B., M.D. Octavo of 200 pages. New York and London, G. P. Putnam's Sons, 1926. Cloth, \$1.75.

This book makes very pleasant reading. On picking it up the reviewer was inclined to say platitudes and he does not know that he has changed his mind, but whether so or not he does think that if the book is read with care and the ideas suggested carried out the generation thus instructed will profit.

It can be recommended to thoughtful and earnest parents.

ARSENIC AS AN ETIOLOGICAL FACTOR IN THE GENESIS OF ECZEMA

By BINFORD THRONE, M D, LAIRD S VAN DYCK, M D, ELEANOR MARPLES, A.B, and
C N MYERS, PH D

From the New York Skin and Cancer Hospital, New York City

THE mechanism of eczema was discussed by the authors in a previous article dealing with the treatment of the pathological lesion by means of sodium thiosulphate in freshly prepared solutions. At that time it was pointed out that eczema was primarily a problem of edema in which the function of the cell itself was involved. This function or rather dysfunction is associated with certain toxic manifestations clinically apparent in the skin, the blood stream and the liver. The cell dysfunction appears to be brought about through certain stimuli producing an "overcharge" in the function of the cell in which electrolytes, non-electrolytes, metallic poisons and allergic phenomena play a prominent role. For instance one of us (M) has shown that in dermatitis exfoliativa following arsphenamine injections there is a deposition of arsenic in the cutaneous layers and that as clinical improvement takes place the amount of arsenic present in the desquamating skin decreases while at the same time there is an increase of arsenic in the blood and urine, which formerly have shown no arsenic or not more than a trace.

A second phenomenon supporting these views is illustrated in the absence of arsenic in the blood stream and urine during the onset of jaundice. In the investigation of Fordyce, Rosen, Mueller and Myers it was shown that arsphenamine in therapeutic doses may produce a disturbance of the vascular system in which the peripheral tonus suddenly turns to a sympathetic overbalance and that of the splanchnic region to a parasympathetic.

In a previous article it has been shown that in all cases of eczema there is a marked increase in the sugar content of the blood stream as well as a high chloride content. The weeping and vesicular manifestations are invariably associated with the chloride content, and the pruritus with the sugar content. As a normal balance is reached the values for sugar and chloride drop and clinical improvement is noted. This improvement is brought about by re-establishing the cell function

through the use of sodium thiosulphate, by means of which the intoxicating substances are released and the controlling mechanism of the cell is restored to normal. This restoration of cell function is associated with the process of osmotic tension, and the protective action of non-injurious products which permit the normal manifestation of these stimuli.

In eczema there is a condition of balance between varying shifting and opposing forces—a characteristic of a living process yielding a status that might be designated as dynamic equilibrium. This results in a disturbance of the regulation of volume. The regulatory mechanism is capable of overcoming certain defects in its component parts, but this mechanism of repair is limited by the conditions of disease. It is implied that our conception of eczema presupposes a primary condition of injury from within due to the failures in the transmission of certain nerve stimuli or to physiological disturbances of nutrition, or of endocrinology which cause toxic conditions to develop. These are followed by more pronounced injuries resulting in a pathological lesion of the skin. In a word, eczema may be regarded as a concept of edema due to a perversion of the regulatory mechanism. In man edema frequently follows injury or blocking of the lymph channels.

In the first manifest instance edema is a disturbance of the volume of the cells of the cutaneous layers. In this respect the fluids accumulate in these layers in the vital effort to restore electronic and osmotic balance. In the failure that temporarily results, the fluids exude to the skin surface and produce the vesicular, weeping condition characterizing eczema. Volume is determined largely through osmotic tendencies and there is no doubt that electrolytes and non-electrolytes enter very largely in this mechanism. In this respect our attention has been directed to the types of vital operation. On the one side carbohydrate reducing substance—non-electrolyte in nature—and on the other, the

chlorides—electrolytes—have absorbed our attention in explanation of this mechanism

Experimentally it has been shown that the entire periphery and splanchnic region are controlled by one nervous system. Investigations by E. F. Mueller have shown that sudden changes in the skin are brought about by nerves controlling the skin.

Histologically it is known that in eczema there is a dilatation of the blood vessels of the papillary and sub-papillary layers, inflammatory cellular infiltration around the dilated capillaries, edema of the papillary and superficial part of the reticular layer, dilatation of the interepithelial lymph spaces, a spongy condition of the prickle cells, moderate acanthosis and parakeratosis. These observations are important in their relation to the part that arsenic plays in the etiology of eczema. The work of Spies in relation to anesthesia in tonsillectomy brought out the important fact that inflammatory reaction and swelling are controlled by nervous reflexes. The nervous system also plays an important part in true anaphylaxis and sensitization phenomena. Similarly the endocrine glands are bound up with the sympathetic nervous system. Whitfield noticed in a case of vesicobullous eczema of the legs in a gouty individual that when the bullae burst and the serum ran down the legs there appeared in a few minutes a red streak which was followed in a few minutes by an urticarial wheal. This was succeeded by a line of vesicles and then a long narrow bulla. The patient's serum caused no reaction when applied to Whitfield's own arm. He suggested that the patient had become sensitized to his own tissue products. Bloch considers that the primary cause of eczema is an injury of the epithelium through substances which reach the epidermis either through the blood stream or by external means.

In eczema there is a change in the permeability for the blood plasma due to a dilatation of the blood vessels, which lose their contractility. With these histological changes there is an increased tension and pulling of the nerve elements. These abnormalities lead to pruritus. According to Bayliss the sensory nerves regulate vaso-dilator irritability. These nerves are dichotomous, one branch going to the smallest vessels, another going to the corpuscles of sensation in the skin. With these ideas in mind it is apparent that inflammatory-causing substances can act either by way of the nervous system or directly on the blood vessel system.

The experimental part of this article deals with a group of patients showing eczema in its normal clinical condition. Further questioning showed that there was an industrial contact with substances which might be responsible for the etiology. In this group there were fifty-five (55) patients on whom careful study has been made both in the blood chemistry as well as in the

arsenic content of the urine after the injection of sodium thiosulphate. This procedure has been shown by us to be a satisfactory diagnostic method in detecting arsenic intoxication. The patients included in this group invariably show a high sugar for the blood. The chloride factor is a trifle more diverse in that its manifestation is noted either in extremely low values or in abnormally high values. As pointed out in the earlier publications ninety (90) milligrams of sugar per one hundred (100) cubic centimeters of blood is regarded as normal by our method, designated as the Hastings-McLean method. The normal chloride content according to the Whitehorn procedure is placed at four hundred and fifty.

Our experience has shown that the sugar content runs parallel with the chloride content and that exacerbations always occur when the five hundred mark is reached for the chlorides. Patients at the menstrual period also show abnormalities both in their blood chemistry as well as in their clinical improvement. These patients are maintained as nearly as possible on a salt-free ten per cent carbohydrate diet. The treatment consists of the intravenous injection of five cubic centimeters of a ten per cent thiosulphate solution which has been freshly prepared. The use of old solutions or of those which have shown a sulphur deposit is to be avoided as they show a less marked action in re-establishing the normal regulatory mechanism.

The following case histories are typical of that group of patients who have arsenic as an etiological factor in the genesis of their eczema.

Case No 1—E. B., female, age 31. Was referred for treatment April 1, 1925. Previous history was negative except for a stomach trouble, which had been diagnosed as a nervous indigestion. This was due to chronic constipation and carbohydrate fermentation. She also had a cystic ovary and chronic appendicitis. A recent operation showed this.

Skin condition. The first attack of the skin trouble developed in December, 1924, and lasted only a few weeks. The condition for which she applied for treatment began in February, 1925, and had been present eight weeks when she was first seen. The rash began on the dorsum of the right hand and on the left leg. From these places it had spread and at the date of her first visit it was present on the scalp, face, neck, limbs and trunk, in fact it was practically universal. The primary lesions were papulo-vesicles seated on an oedematous, reddened base.

In places where the vesicles had ruptured the surface was raw and oozing. The oedematous condition of the skin was very marked. There was also considerable infiltration and a marked tendency to lichenification. She was admitted to the hospital and after four weeks was discharged somewhat improved. On May 7 she had a relapse and was sent to the hospital again where she stayed 12 weeks. During these hospital periods all kinds of internal and external treatment were tried without any appreciable benefit. Among other things she had eight X ray treatments. The X rays seemed to be of slight benefit for a few days only.

On January 16, 1926, she was given Soda thiosulphate and an examination of her urine disclosed the presence of arsenic. Since that date the injections of Soda thiosulphate have been continued. She began to improve

at once. This improvement has been consistent with the exception of an exacerbation on March 1st and a slight exacerbation on March 19th. At this date, August 14th, her skin is entirely normal. The infiltration has entirely disappeared. There are no moist oozing areas. The pruritus has stopped. At night, however, after dietary indiscretions, there is a tendency for the development of a few papular urticarial wheals on the forearms.

She was operated at St. Catherine's Hospital, Brooklyn, a few weeks ago by Dr. Chas. A. Gordon, who removed a cystic ovary, a diseased tube and a chronically inflamed appendix. This severe surgical procedure has not caused a relapse. The development of the urticarial wheals would seem to show that the arsenic has not been entirely eliminated and that when it comes in contact with some intermediary metabolic product it can react in the form of urticaria.

Occupational history for years she had worked in a paper box establishment. Her work for many months previous to her illness consisted in pasting papers printed with gilt letters in boxes. These papers would frequently have much of the gilt in loose powder form when she received them. It was her habit to moisten her fingers with her tongue to facilitate her handling the papers.

Examination of the gilt powder for arsenic showed 4.286 mms, per 100 grams.

Examination of the paste for arsenic showed 0.035 mms per 100 grams.

The following are the laboratory reports of this case.

BLOOD			URINE

Case No. 2—E. J., male, white, age 43. Duration of disease 2 months. Rash first appeared on the right ankle and spread to the legs, thighs, hands, forearms, arms and face. The primary lesion was a papulo-vesicle. The evolution of the lesions was associated with oozing infiltration and oedema of the skin. Pruritus was extremely marked.

After the acute stage subsided there was lichenification.

He had suffered with a similar condition five years ago.

He was admitted to the hospital on March 4, 1926, and discharged to the out-patient department on March

20th. His occupational history was varied, at times he worked as a painter, at others as a helper in a barrel factory, but for the past several years he had been on construction work where he came in contact almost constantly with cement.

At this date, August 14th, he is practically well.

The following is a report of the laboratory findings in this case.

Path No. 9248 "E. J."

Microscopical Examination

Section shows a moderate amount of edema in the corium especially in the upper part. The edema is both intra and intercellular. There is a perivascular infiltration of lymphocytes and endothelioid cells which involves even the blood vessels in the lower corium. The vessels themselves are not dilated. The epidermis appears unaffected.

Diagnosis. Chronic eczema.

Histological report by Dr. D. S. D. Jessup, Director of Laboratories, Skin and Cancer Hospital.

Case No. 3—N. Y., white, male, aged 22 years. Admitted to the hospital, March 4, 1926. Duration of the disease on admission was five months. He had had two previous similar attacks. The rash started on the anterior surfaces of the elbows and in the popliteal spaces. It spread and on admission was practically universal, normal skin only showing on the upper part of the arms and on part of the trunk. The primary lesion was a papulo-vesicle. The skin of the involved parts was oedematous infiltrated, reddened, oozing and covered with papulo-vesicles. Pruritus was marked.

Thiosulphate treatment was instituted at once. The response to this treatment was immediate and he was discharged to the outpatient department in fair condition on April 19. He had an exacerbation after discharge, probably on account of inability to follow orders at home, and was readmitted on April 28. He was discharged June 18, and at this date, August 14 he is practically well.

Occupational history. For one year he had worked in a chemical factory handling an insecticide containing arsenic. He quit this work because the powder irritated his eyes. He claimed that it "made his wrists sore." This work was done during the third year previous to his admission to the hospital.

The following are the laboratory findings in this case
 Path. No 9245 "N Y"
 Microscopical Examination

There is a thickening of the epidermis so that the rete pegs are at all angles and shapes and a thickening of the surface of the papillary plates in places. The granular layer is regularly thickened. In places there is a horny crust and in others a small vesicle has ruptured on the surface. There is a slight perivascular infiltration that affects the vessels of the papillary body and upper corium.

Diagnosis Chronic eczema

Case No 4—A S, male, white, age 21 years. Admitted to the hospital, April 4, 1926. He had suffered with recurring attacks of eczema for years. The present condition began two years ago in the popliteal spaces and spread up and down the legs, to the arms, forearms, wrists and hands, the face was also involved, as was parts of the trunk. The rash consisted of papules and vesicles. The skin was markedly edematous. There was crusting and oozing. Lichenification was present, especially in the flexures. He responded to sodium thiosulphate treatment and was discharged to the outpatient department on April 19th. At this date he is well.

Occupational history for about thirty months he had worked in a paint store.

Laboratory reports as follows

Microscopical report by Dr D S D Jessup, Director of Laboratories, Skin and Cancer Hospital
 Path No 9249 "A S"

Microscopical Examination

There is a moderate amount of inter and intracellular edema of the connective tissue of the upper corium and about the vessels. The vessels themselves are not dilated and are surrounded by an endotheloid and lymphocytic infiltration.

A few cells have wandered into the epidermis which appears normal otherwise. The hair follicles are not involved.
 Diagnosis Chronic eczema

Case No 5—O J, male, white, age 48. Admitted, March 24, 1926.

Condition began 14 years ago on abdomen, cleared up after two years and recurred in a short time and spread until the rash became practically universal. For several years there were periods of remission but never complete disappearance of the skin condition. On admission he showed universal involvement except for a few small areas on the upper part of the trunk. The skin was red, scaly, oedematous and in many places, lichenified. Trauma such as scratching caused a serious discharge. Habits for years he had drunk large amounts of whiskey, frequently a quart a day. Occupation he had worked at various trades, was varnisher in a furniture factory for several years, previous to the appearance of the skin disease. He also gave a history of having taken arsenic. Under sodium thiosulphate therapy he was practically cured.

Case No 6—Sol C, age 45, male, white, admitted January 25, 1926. The disease started on the abdomen as a scaly erythematous patch. The rash spread and became absolutely universal, and on admission he showed generalized redness, scaling, crusting and edema of the skin, with patches which were wet and oozing. He improved steadily and was discharged to the outpatient department on March 1st. After discharge he was persuaded to enter another hospital. In this hospital arsenic as a causative factor in his condition was not considered and he was given injections of, probably, sodium cadolate intramuscularly. His condition became very much worse and he returned to the Skin and Cancer Hospital on June 25th. He has progressed nicely and at this date is ready for discharge from the hospital. His condition now shows only a little erythema and moderate lichenification of the flexures of the large joints.

His occupation for thirty years has been tailoring. For some years he has worked as a cap blocker. During his work he continually put pieces of woolen cloth in his mouth. Woolen cloth is sprayed with a solution of arsenic to protect it from moths.

The laboratory findings in this case are as follows:

Case No 7—M McK., white, male, age 24 years. Admitted for treatment March 15, 1926. On admission showed a typical papulo-vesicular eczema involving the face, neck, arms, forearms and hands. There was considerable edema present and in most places a marked serous discharge.

His history showed that he had suffered with similar attacks during the previous few years. He is entirely cured at this date. His occupation was a pipe fitter, and for many months he had been employed in a large general chemical factory.

Below is his laboratory history:

BLOOD				URINE		
Date	NaCl mg per 100 cc.	Sugar mg per 100 cc.	Specific gravity	Per cent Total solids	Mg arsenic per 100 gms. dried specimen	
3/15/26	467.0	108.0

6/ 9/26			1.015	1.58	Trace	

In all of these cases clinical improvement has been attained and as far as it is known, recovery has been established. In each instance it has been shown that the exposure to arsenic occurred many months previous to the first mild onset of the eczematous condition. The eczema became a recurrent manifestation which finally resulted in the severe chronic condition which demanded hospitalization. In every instance all other modes of treatment had proven inefficient and in each instance the arsenic as an etiological factor had not been considered.

As early as 1888 Paschkis and Obermayer, *Arsenic and Eczema*, *Med Jahrb*, Wien, 1888, n F iii, 117, stated that arsenic could cause an eczema, but to our knowledge its actual presence has never been previously demonstrated and it is regarded by us an important factor in the production of lesions in the skin whose mechanism will be discussed at length in another article, which will further elucidate our observations.

In looking over the tables of excretion in these cases it will be noted that there "tides of ebb and flow" of arsenic and this is particularly significant in its contrast to arsenic dermatitis following the injection of the arsphenamine group, as employed in syphilis therapy. This contrast centers about the differences in the kind of arsenic involved in the intoxication. Mueller, Rosen and Myers have shown that the reaction of the arsphenamines produces an effect on the involuntary nervous system irrespective of the dose. Whether this change is necessary for a therapeutic action is not known at present. This second group of arsenicals undoubtedly has produced a chronic intoxication which only manifests itself when a sufficiently large stimulus presents itself. This stimulus may not be a direct impetus but is associated with some previous injury or disturbance in which the cell function and physiology has participated but through "overcharge" it has ceased to properly continue its response and on this basis the use of sodium thiosulphate brings about a change in the regulatory mechanism.

It is particularly interesting to note at this time the work of Petersen on lymph alterations following arsenic injections in which he showed that injections of inorganic arsenic produce an increase in the lymph flow with increased protein, sugar, phosphate and bile. These manifestations check up very well with our observations on clinical cases which are reported in this article.

In all of the cases mentioned above the arsenic factor was produced by that group of compounds known as the inorganic preparations. The patients were either individuals working in insecticide plants many months previous or garment workers where contact with contaminated cloth was involved, or fruit dealers, or workers in arsenical factories. In this connection reference is made to manufacturers of paints, dyes and acids as well as storage battery plants. In every single instance mentioned above, at least one chemical case is involved and arsenic has actually been demonstrated by our diagnostic procedure. It is our belief that about *ten per cent* of all the eczema cases in our clinic have arsenic as a contributing factor in the etiology.

SUMMARY

Discussion on *fifty-five* cases of eczema is presented above and this group represents about *ten per cent* of the cases examined by us during the

past year. It has been demonstrated by us that the typical disturbance of sugar and chloride metabolism is generally present and that the eczema is a problem of edema resulting from injury from within. This injury may be accentuated by other intoxicating elements. Previous slight damage may exist and through certain excessive stimuli the lesions may become acute.

These investigations show that there are "tides" of arsenic excretion in which there is an "ebb" and "flow" of arsenic. The eczema will clear up only when these deposits are reduced to a sub-minimum effective stimulus. The arsenic deposits are removed by the persistent use of sodium thiosulphate in a freshly prepared solution which re-establishes cell function as well as converting the arsenic preparations into a soluble condition ready for excretion.

That arsenic is an etiological factor in the genesis of eczema is demonstrated by its presence in the urine.

Eczema follows the ingestion of arsenic through foods, and internal contact through its presence in the blood stream, thereby producing pathological lesions in the skin as a result of dysfunction of the cells of the skin. Histopathology in these cases confirms the diagnosis of chronic eczema.

The condition is treated therapeutically by means of a restricted carbohydrate, nearly salt-free diet and intravenous injections of thiosulphate of soda.

SYSTEMIC OTOGENOUS INFECTIONS*

By SAMUEL J KOPETZKY, M.D., F.A.C.S., NEW YORK CITY

A SYSTEMIC infection always manifests itself by a typical reaction. It results from the activity of the body defences against bacterial or toxic trauma which has progressed from a local to a general distribution. This reaction, with but slight variations, is noted in malaria, typhoid fever, influenza, puerperal sepsis and other diseases wherein a local infection has gained entrance to the blood stream. The symptoms may vary in intensity, at first exhibiting mild temperature elevations, headache, malaise, anorexia and so forth. Later septic temperature, rigors, sweats, petechial hemorrhages and metastatic foci make their appearance. Once the local infection has become general, the treatment to combat the systemic disease is in each instance essentially the same. The only difference in the treatment of the various conditions producing systemic infection lies in the exact determination of the primary causative lesion. The latter must be eradicated so as to stop the source of the sepsis. In typhoid fever this is accomplished by rest and hygiene of the intestinal tract. In endocarditis the heart is made to function with the minimum amount of energy. So in systemic infection due to otitic disease, the therapy depends upon the character of the causative lesion in the temporal bone. The systemic infection per se is treated in no wise differently than sepsis due to other causes.

In otitic disease, as in other conditions, two types of systemic infection may occur, a toxemia or a bacteremia. The former is always present in the early stages of acute otitis, may be present throughout the subsequent involvement of the mastoid process, but usually disappears with the subsidence of the acute infection. A bacteremia will be present when the primary disease in the mastoid process has spread to and into the venous blood channels. It will also be evident when the initial mastoid disease is of the type characterized by primary involvement of the small blood vessels in the cellular membranes.

The toxemia of the acute otitis is due to the absorption of bacterial by-products. The body reaction is a defence mechanism resulting from Nature's attempt to cleanse the system. We know that this is accomplished by a walling-off of the original focus with a barrier of round cells and by the formation of antibodies. Where this defence is successful the otitis is healed and the toxemia disappears. Where Nature's efforts fail, the toxemia continues, in some instances at a level and in others intermittently. Here the otologist must aid the

patient. An undue prolongation of toxemia with failure of the middle ear disease to subside is indicative of a progression of the local lesion despite the absence of signs or symptoms pointing to such progression. A persistence of mild temperature, increasing pallor, coated tongue and other signs of toxemia over a considerable period of time after the involvement of the middle ear should lead the otologist to open the mastoid process and exenterate the disease which will be found. Once this has been done, the toxemia will begin to abate because its source has been removed. Proper hygiene and diet are the only other requisites in the post-operative treatment of this type of systemic infection.

The otogenous systemic infections characterized by a bacteremia may be produced in one of two ways. In one instance, the cellular elements in the mastoid process are subjected to the pressure of stagnant pus. A necrosis of the bony walls results and there is then produced the usual type of acute mastoiditis, namely, the coalescent type. Where this lesion is permitted to advance, it soon reaches the inner table and subjects it to pressure. A necrosis of the sinus or dural plate occurs, due to the lack of blood supply, and the soft parts of the endocranium are exposed to the purulence in the mastoid cavity. This constitutes a perisinus or extradural abscess. The pressure, however, continues, and is now exerted directly on the wall of the sinus, which becomes compressed first and then infected. Due to the narrowing of the sinus lumen, with the consequent slowing of the blood stream, and the injury to the endothelial lining, a thrombus develops within the sinus. There is present, then, an infection of bacterial origin within the circulating blood, which, with the disintegration of the thrombotic mass, soon becomes disseminated throughout the body. A bacteremia results.

The therapy in such a case is of two varieties, preventive and curative. Prevention is possible by timely surgical intervention before the disease has reached and involved the inner table. This type of otitic systemic infection is frequently the result of delay in operating for the relief of the acute coalescent mastoiditis. Once the systemic infection has become established, the curative treatment is the immediate removal of the thrombus in the blood channel. This is accomplished by thorough cleansing of the infected sinus and obliteration of the route to the general circulation. The latter step is effected by the ligation or resection of the internal jugular vein. After these procedures have been performed the systemic in-

* From the Oto-Laryngological Department of Beth Israel Hospital, New York City.

fection still remains, but its source has been removed. The treatment of the systemic infection per se will be considered later.

One more word as to diagnosis. Too much reliance is often placed upon the presence of a positive blood culture in systemic infections following the acute coalescent mastoiditis. This type is characterized by the gradual progression of a necrotic process toward the inner table or cortex. In advance of the necrotic area is Nature's round cell infiltration in the form of granulations. These granulations are protective in character. They appear on the sinus wall when the sinus is exposed and they appear in the sinus as a formed thrombus before the infection has gained entrance to the lumen. Therefore, in the thrombus due to a coalescent mastoiditis, we find a protective mechanism which becomes infected secondarily. And so, throughout the system, the protective forces have been established before the advent of the infection. Consequently the finding of a positive blood culture in this type of systemic infection will not usually be obtained until the sepsis has been present for some time. In thirty-seven of my cases of sinus thrombosis following coalescent mastoiditis, blood culture was positive fifteen times, negative fifteen times and not recorded in seven. One should not wait for the laboratory to make one's diagnosis of systemic infection in the face of chills, septic temperature, severe headache and prostration, appearing some time after the advent of mastoid disease. The clinical picture is sufficient evidence upon which to base the indications for surgery upon the sinus and jugular vein.

The other type of mastoid disease which produces a systemic infection of bacterial nature is that characterized by the primary involvement of the small vessels in the mastoid process. It is caused by the entrance of a hemolytic organism, usually the streptococcus hemolyticus, into the lumina of the mucosal vessels. This immediately results in a multiplicity of infected thrombi. The infection in this instance is located in the circulating venous blood and not in the cell spaces. Consequently the cells are not subjected to pressure necrosis and their walls are not destroyed by the disease. The disease here is manifested by an intense engorgement of the cell lining and by a hemorrhagic exudate into the cell spaces. It is from these phenomena that the conditions derives its name of the hemorrhagic type of acute mastoiditis. Roentgenography does not aid one in diagnosing this type of mastoiditis. The cells are never destroyed and therefore appear intact, on an X-ray plate, at any time during the course of the disease. In the coales-

cent mastoiditis, gradual destruction of the cells can be seen.

Clinically, a systemic infection is present in the hemorrhagic type from the outset. The disease itself is a systemic infection by virtue of its location within the blood stream. A venous thrombosis is present from the beginning. The lesion progresses by an intravenous growth of the thrombi toward the larger blood channels, and not by the progression of a necrotic process. Consequently a perisinus abscess is rarely observed in this type of acute mastoiditis. The sinus is invaded by the growth of a thrombus from a smaller tributary into its lumen. The clinical picture in the sinus thrombosis of this variety is exactly the same as the clinical picture in the earlier stages of the disease. The presence of bacteria in the general blood stream is not dependent upon the presence of a thrombus in the lateral sinus since particles of infected thrombi are dislodged and find their way into the circulation as the small thrombi extend toward the larger vessel.

A determination of the extent of the thrombosis in a case of hemorrhagic mastoiditis cannot be made by inspection of the parts or by the course of the disease. Since the sinus is invaded by the intravenous extension of the thrombi into its lumen, the sinus wall is usually normal in appearance, even where an extensive involvement, of its interior exists. There are no granulations or discolored areas on the wall to make one suspect the presence of a thrombus within the sinus. Therefore one must not look for the same indications for sinus and jugular surgery in this type of mastoiditis as are found in the coalescent mastoiditis. In the hemorrhagic mastoiditis, the estimation of the hemoglobin and red cells furnish the most positive indication as to the extent of the thrombosis. Since the causative organism is hemolytic and is lodged within the circulation from the outset, a progressive lowering of the hemoglobin percentage and of the number of red cells is noted from day to day. After the diagnosis of this type of mastoid disease has been made, the hemoglobin and red cells should be estimated daily. Operation is indicated as soon as the lesion is recognized. Early operation will succeed in eradicating all the infected thrombi in the mastoid venules and thus prevent further extension of the infection into the sinus. Where the simple mastoidectomy has been sufficient to eradicate the disease, the sepsis stops promptly and the reduction of hemoglobin and red cells ceases. On the other hand, the failure of the surgery to remove all the thrombi is marked by a continuation of the sepsis and by a progressive diminution in the hemoglobin and red cells. The latter finding furnishes the most valuable guide as to the extent of the thrombosis. After

simple mastoidectomy, a continuation of the reduction speaks for involvement of the larger venous channels, and surgery on the sinus and jugular vein is then indicated

In the general treatment of otitic systemic infections, I have obtained the best results from the following procedure. After the blood vessel surgery has been performed, the daily blood examinations are continued. Where the hemoglobin percentage continues to fall despite the sinus surgery and reaches a point below half of normal, I employ transfusion of whole blood by the direct method. The amount varies with the individual patient. In estimating the hemoglobin loss, it must be remembered that the normal for infants and very young children is not one hundred per cent, but closer to sixty-five or seventy per cent, and the percentage of hemoglobin obtained in these little patients must be considered proportionately. An immediate increase in the hemoglobin and red cells is noted after transfusion. Should the hemoglobin percentage again drop below half of normal, another transfusion is given. You will note that transfusion is employed to replace lost hemoglobin and red cells and not to furnish antibodies. The latter is incidental, although it is, of course, valuable where it occurs. If one but remembers that the hemolytic organism destroys the hemoglobin, and that it is this marked anæmia which permits the bacteremia to overcome the patient's resistance, the use of transfusion for our purpose will be understood. By relieving the body of the necessity of replenishing the lost hemoglobin, its energies can be devoted to the for-

mation of antibodies and the localization of the general infection

The white cell count is valuable only in determining the outcome of an otitic systemic infection. Where the patient is successfully combatting the infection, the total number of white cells is high, usually above fifteen thousand, and the percentage of polynuclears is rarely above eight-five per cent. We know that the total number of white cells in the blood is evident of the ability of the body to overcome infection. The percentage of polynuclears in acute infections is high and is indicative of the presence and strength of the infection. It is the actual increase in the number of white cells as a whole that is helpful in overcoming sepsis, and not the relative percentage of polynuclears. A high polynucleosis without a proportionately great increase in the total white cells is indicative of an infection over which the body is gaining no control. McKernon has studied this phase of the subject and has determined the relationship between the total leucocytosis and the percentage of polynuclear cells. In otitic systemic infections, McKernon's resistance charts furnish a guide in prognosticating the outcome of a given case.

I have had very little success with any of the serums, vaccines or dye products in my cases of otitic sepsis. Transfusion, intelligently used, as a supportive measure, coupled with the outdoor treatment and typhoid diet, furnishes us with the best method of treating these cases after operation to remove the septic focus in the temporal bone.

THE GESTATIONAL GLAND*

By ROBERT T. FRANK, M.D., NEW YORK, N. Y.

WE have (1) given the name of "Gestational Gland" to the three organs which produce or contain the female sex hormone. This hormone is found in the ripening follicle, in the corpus luteum, and in the placenta. These apparently dissimilar structures have a continuous and coordinated physiological function as well as action.

THE FEMALE SEX CYCLE

With the onset of the first ovulation a regular cycle occurs in the adult female. The cycle may be subdivided into (a) the fertile or complete cycle which begins with ovulation and terminates with puerperium or lactation, and (b) the infertile or abortive cycle where no opportunity for impregnation has arisen, or where nidation has failed to occur.

(a) *The normal, fertile or complete sex cycle* begins when the ripening follicle stimulates the uterus, especially its mucosa, to produce the pre-gravid (in the human often mis-called the pre-menstrual) hyperplasia. This hyperplasia is the physiological preparation for the proper embedding place for the ovum. When ovulation occurs the potent follicle fluid is poured out into the peritoneal cavity, is there rapidly absorbed, and exerts an intensified action on the uterus. The fallopian tube, too, at this time, as Corner (2) has shown, has a stronger peristaltic wave than at other times. This increase in motility which is also due to the female sex hormone as we (3) have shown, transports the ovum towards the uterus. Impregnation normally occurs in the fallopian tube, the impregnated ovum which is already undergoing segmentation, reaching the uterus at a time when the egg's surface has acquired a lytic or dissolving action. The segment-

* Read at the Annual Meeting of the Medical Society of the State of New York at New York March 31 1926

ing ovum therefore readily makes its bed in the prepared (pregnand) decidua. This decidual reaction is entirely dependent on the hormonal action of the corpus luteum as Leo Loeb (4) has demonstrated. During pregnancy the corpus luteum continues to secrete the female sex hormone for some time but at an early period of gestation, the covering of the growing ovum, namely the chorio-epithelium, which later localizes as the placenta, likewise produces this hormone, first adding to and later replacing the corpus luteum secretion. Thus the tubular tract (as well as the mammae) is continuously stimulated throughout pregnancy by the large amount of the female sex hormone that reaches it and is thus enabled to undergo the tremendous hyperplasia necessary for successful pregnancy. Whether it is the fetus or the chorio-epithelium which causes the corpus luteum to persist for such a long time during pregnancy, is unknown, but we do know that after a critical period, which varies in different species, the ovaries as well as the corpus luteum of pregnancy may be ablated without interrupting gestation (Hartman 5).

(b) *The abortive or infertile sex cycle* results when impregnation does not take place. The pregnand growth of the uterus, under the stimulus of the ripening follicle, is intensified at the time of ovulation and the formation of the corpus luteum with consequent continued secretion of the female sex hormone takes place exactly as in the beginning of the fertile cycle, but as the unimpregnated ovum rapidly disintegrates and no chorio-epithelium develops, the corpus luteum involutes and loses its function shortly after ovulation has occurred. Consequently the tubular tract and breasts, no longer stimulated by the continuous and massive secretion of female sex hormone, rapidly undergo regression, which in the lower animals is marked by a simple atrophy (characteristic of diestrus) and in the primates shows itself in necrosis and exfoliation of the endometrium, which is accompanied by the external bleeding, known as menstruation.

When the ovaries no longer produce enough ripening follicles, the genital tract as well as the breasts are no longer supplied with sufficient circulating female sex hormone. Consequently the cyclical phenomena become more irregular and less marked until they entirely cease, which time corresponds with the senium or menopause.

PHYSIOLOGICAL PROOF

What has preceded is a resume of the most essential sexual phenomena. The normal phenomena can be reproduced to a striking degree by artificial means (substitution). Injection of potent extracts of follicle fluid, corpus luteum or placenta will induce

- (1) premature puberty (6),
- (2) will cause the stimulated infantile animal

independently to continue in a sexually mature state (7),

(3) will, in the spayed female, cause the external and internal genital and mammary changes of estrus (8) as well as the willingness to copulate (9),

(4) in larger dosage produce the uterine and mammary hyperplasia of early pregnancy (pseudo-pregnancy) (1).

CHEMISTRY OF FEMALE SEX HORMONE

A comprehensive resume of the chemistry of the female sex hormone will be found in the article by Frank and Gustavson (1). The active principle has never as yet been completely purified. We have, however, obtained it free of phosphorus, nitrogen, and cholesterol. Thus freed it contains merely carbon, hydrogen, and perhaps oxygen, and shows as a clear oily substance which deteriorates on exposure to oxygen and light. The hormone resists high degrees of heat and treatment with strong acids and alkalis. The active principle is an unsaturated body. It is soluble in all lipid solvents and in the presence of certain extractives of the placenta.

Our (1) researches have shown that the claim of certain investigators to have obtained the female sex hormone in pure form is unjustified.

PHARMACOLOGICAL METHODS FOR TESTING THE POTENCY OF THE FEMALE SEX HORMONE

- 1 (a) Production of pubertas precoxa
- (b) Activation of the uterus of castrates

These two methods have been used for many years. The rabbit is the best animal for this type of study.

2 Vaginal smear method used on castrated rats and mice.

Stockard and Papanicolaou (10) pointed out variation of the vaginal spread in guinea pigs. Long and Evans (11) showed this in white rats. At estrus the spread contains only squamous cells. During the other stages leucocytes are found. Allen and Doisy (12) introduced this method into the study of the sex hormone.

3 Contraction rate of the isolated uterus of the white rat.

The slow spontaneous estrual contraction and the rapid interestrual contraction was pointed out by Blair (13). It was first used to test the potency of the female sex hormone by Frank, Bonham and Gustavson (3).

By means of these three specific tests, it has been shown that the female sex hormone can be obtained alike from the follicle, fluid, the corpus luteum, and the placenta (1).

HISTORICAL

In this short historical review only the most striking landmarks will be touched upon. In

1895 Knauer (14) demonstrated that the ovaries may be separated from all vascular and nervous connex, and when transplanted into a new site, will there exert cyclical influence as before Halban (15) at will, by transplantation, restored menstruation in monkeys. This was interpreted as evidence of an internal secretion, it being assumed that a substance secreted by the ovaries found its way into the blood stream and thus reached the genital tract and breasts. In 1897 Beard (16), as well as Born (17) called attention to the corpus luteum as a gland of internal secretion. Fränkel (18) by experimental means showed that the corpus luteum was necessary for the continuation of pregnancy. Leo Loeb (19) went further and demonstrated that the yellow body activated the maternal uterine decidua as well as inhibited the ripening of follicles. Bucura (20) emphasized the importance of the growing follicle in producing uterine changes.

A different and more easily interpreted method of demonstration was found in reproducing phenomena by substitution. Iscovesco (21) 1912, with alcoholic extracts of ovary produced hyperplasia of rabbits' uteri. In 1913 Fellner (22) showed that alcoholic extracts of placenta produced estrual changes in the tubular system and breasts of rabbits and guinea pigs. In 1922 Frank (23) showed that similar estrual changes could be obtained in immature vaginal rabbits by the injection of follicle fluid obtained from both pregnant and non-pregnant animals.

In 1925 Frank, Gustavson and Weyerts (24) as well as Loewe (25) by specific tests demonstrated the presence of the female sex hormone in the circulating blood. This is the first time that a true hormone has been demonstrated by specific means in the circulation and is a real substantiation of the hormone theory which hitherto had been taken largely on trust.

DEDUCTIONS

In spite of the tremendous strides in the elucidation of the phenomena of sex as found in the female, exemplified by this brief summary of some of the most striking and important researches, the direct application to therapy has been disappointing. The reason for this is that the female sex hormone is present only in considerable dilution in the gestational gland (that is follicle fluid, corpus luteum, and placenta). During extraction a large amount of the hormone appears to be either lost or destroyed. Finally, the sensitiveness of the active principle to oxidation renders its preservation difficult and short-lived.

As I have repeatedly claimed (26) and as has been shown by others (27) the many preparations upon the market are physiologically inert. Consequently the results reported are variable and unconvincing. There is, however, every prospect

that the immediate future will see a female sex hormone applicable to therapeutic use. Such a preparation will be found to be powerful and, I fear, also poisonous just as experience with insulin has shown this drug to be powerful and toxic if not correctly used. A potent preparation of the female sex hormone will produce a rapid hyperemia and hyperplasia, showing itself in an immediate growth of the uterus, succulence of the vulva and vagina, as well as increase in size of the breasts, and thus should prove of immense value in cases of infantile and atrophic genital tracts, and in the treatment of general infantilism, if begun before puberty. However, I predict that until such a female sex hormone is exhibited in the proper quantity and to the proper individuals, much harm may be done by its reckless use. Quite the contrary obtains with the present inert materials which are sold under various trade names and which may be given without fear of doing harm, except perhaps by spoiling the digestion and which, in a few cases, may produce an excellent psychic effect on the impressionable.

POSTGRADUATE INSTRUCTION IN THE SEVENTH DISTRICT BRANCH

By BENJAMIN J SLATER, M D, ROCHESTER, N Y

A report given at the annual meeting of the Seventh District Branch of the Medical Society of the State of New York, held in Geneva, on September 29, 1926

IN May, 1923, a course of lectures was given at the home of the Rochester Medical Association on Prince Street covering Pediatrics and Obstetrics. The period was for two weeks and the lectures were given at 4 30 P M, each day. They were given under the auspices of the New York State Department of Health and the Medical Society of New York acting through the Monroe County Society. Under the provisions of the Sheppard Towner Act, which is a Federal enactment, the State Board of Health may make certain contributions to lectures on maternity and child hygiene. It was under the provision of this act that the lectures were given.

The lectures had three distinct advantages

A—To the community

B—To the physicians as a group

C—To the physician as an individual

A-1 The fact that the Sheppard Towner Act has been passed is evidence of the public confidence in this type of endeavor

2 The public gains increased confidence in the physicians when it has knowledge that as a group they are trying to better themselves by bringing the best of the profession to lecture to them

3 The public has a right to expect that physicians will keep up to date. These post graduate courses are evidence of the physicians desire to do so

B—The physicians as a group are helped

1 There is great emotional value in bringing a great group of physicians together. College days are renewed. The relation of teacher to student is re-established and especially among the older men these lectures awaken bygone memories which they have treasured

2 The lectures, through the fact that they are largely attended, developed a class consciousness in physicians. While physicians have always been strong individualists, they have many times missed the value of mass action. Any group bringing them all together under such auspices is a good thing

3 In exact proportion as trips to Vienna, Paris and London help the individual and give his patients more confidence in his work, so do these local courses make the work of the practitioner easier

4 There is a spirit of comradeship developed among the various groups in the city. The

largest membership was two hundred and two. The average for the first week was one hundred and thirty-eight, and one hundred and eleven for the second week. In Geneva the course of lectures previously given averaged an attendance of thirty-eight. This was considered very good. Wayne County had the best attendance. There was seventeen members out of thirty-six. Ontario averaged fourteen. Yates seven.

5 The plan of inviting only outstanding practitioners and teachers is a good one, for it brings to the medical men only physicians who have had a large experience and who actually know how to teach. There was not too much speculation in theory, but a thorough explanation of practical problems with their solution.

C—The physician as an individual gains through increased knowledge. The subject was of interest to every practicing physician. Twenty-five letters were written to representative physicians in Rochester. Without exception there was no criticism. On the contrary there was high praise. There was no tendency to make suggestions aiming to betterment, for everyone seemed to think that they were very well as they were planned.

It is of course impossible to bring such a large number of physicians together under such able professional tutelage and not derive great benefit. With one exception the lectures were very well given, very practical, and carried an important amount of knowledge to the physicians.

By and large these were the most largely attended medical meetings ever given in Rochester. The whole occasion seemed to be full of interest, and all in all the members of our Society felt in Rochester that they were entering a new epoch of usefulness to the members.

DISCUSSION

Dr George M Fisher, President of the Medical Society of the State of New York, spoke of a practical way of arranging a course of instruction for a county society. He said that a plan that had worked well wherever it was tried was that the Secretary of the County Society should send a questionnaire to the members asking them to indicate their first, second and third choices of subjects, and then to adopt the subject that was named by the greatest number. The State Committee on Education would provide the instructors.

POSTGRADUATE EDUCATION*

By H J NOERLING, M D, VALATIE, N Y

THIS must of necessity be termed that knowledge striven for and acquired following graduation from a medical school, where only the foundation of medical learning can be laid

With the rapidly striding advance which medical science has been making, it must needs be a trying problem to arrange a medical curriculum which will give the student a solid working basis for his chosen profession. The present day trend toward specialism in all of the branches of medicine is rapidly advancing so that the first thought of the student upon entering college is to seek that particular branch of medicine most suitable to his own ideas, desires and capabilities. Thus we find him, after graduation, and after serving his internship, either taking a post-graduate course in some large medical centre, or allying himself with an older physician doing the same work toward which his ambitions trend. What is the result? Keeping the physicians grouped in medical and civic centres where access to laboratories and hospitals is obtained, and few if any settling in outlying sections where "the old country doctor" is fast waning in age and numbers, and where his associations and activities must soon be but a thought of the past in the minds of all except those who have grown old with him and must soon follow him into the great "beyond."

If I may speak of one who was perhaps known to many here, either personally or thru patients referred to him, I can render a fitting tribute to the memory of one of our profession, a member of long standing in my own County Society, who has stood out as a remarkable example of the "old country doctor" unselfish in rendering aid professionally and financially, often cheering the holiday season of the poor by gifts to the children, food and clothing to the family, spending night after night on his rounds winter and summer, getting cat naps between calls either in sleigh or buggy or later in his auto, serving rich and poor alike, often doing his own surgery (some of it major) back in the hills by lamplight, understanding the mental and spiritual as well as the physical ailments of his patient, fearless in his work when he knew he was right, and withal finding time for study and advancement, I refer to the late Dr I C Washburn with whom I was most intimately and thankfully associated during the last few years of his life. When at his bier, I watched the line (passing by for over an hour) getting one final look at his remains,

ages ranging past eighty years, crippled with rheumatism, failing eyesight, some on canes and crutches, children and children's children whom he had ushered into the world, lawyer, banker, tradesman, clergyman, physician with whom he had associated, I couldn't help but wonder if our present-day advance in medicine must trample this type of man into the dust and have arise out of it the more modern, calculating, scientific type depending too much upon the modern appliances, hospitals and laboratories, losing that closer, friendlier and sympathetic bond which should exist between patient and practitioner.

I trust that in my zeal, I may not be misunderstood, rather I want to awaken that interest in the need of better or rather more adequate medical service to the rural communities, so that men answering the call to this type of work may not feel that they are shut off from medical advancement and may have just as good as their city brothers through some form of continued medical education.

In contrast to my past remarks, may I cite an incident in my own experience. I was considering taking into my practice a recent graduate. In discussing compensation adequate to the work required, a statement was made that owing to his more recent training, he knew a great deal more than I did, was more up to date. For a minute, I felt perhaps he was right, and yet a thought came back that I had had fifteen years of general practice and by my own efforts had kept fairly well abreast of the times with access to laboratories and visits to hospitals though perhaps not familiar with the actual technique of tests employed in laboratory diagnosis. I trust and know this feeling is not general toward rural practitioners, but it lends a possible trend of thought that medical work in rural sections becomes rutted and behind the times.

With this in mind, the first thought is that individual study and practical experience are the first steps in post-graduate education. If thirsty, man or animal seeks water to quench that thirst. So in medicine, wherever he may be, the practitioner can thirst after knowledge, and if he really wants it, can get it. A training in general practice meets all the specialties: surgery, medicine, obstetrics, skin, pediatrics, and so on thru the list. Further than that, it trains a man into a closer relation with the social, economic and mental problems of the individual, placing the doctor in the confidence of his practice. Inspiring confidence, belief in the doctor's ability to correct the ailing body, must be an essential part of perfect understanding between the

POSTGRADUATE INSTRUCTION IN THE SEVENTH DISTRICT BRANCH

By BENJAMIN J SLATER, M D, ROCHESTER, N Y

A report given at the annual meeting of the Seventh District Branch of the Medical Society of the State of New York, held in Geneva, on September 29, 1926

IN May, 1923, a course of lectures was given at the home of the Rochester Medical Association on Prince Street covering Pediatrics and Obstetrics. The period was for two weeks and the lectures were given at 4 30 P M. each day. They were given under the auspices of the New York State Department of Health and the Medical Society of New York acting through the Monroe County Society. Under the provisions of the Sheppard Towner Act, which is a Federal enactment, the State Board of Health may make certain contributions to lectures on maternity and child hygiene. It was under the provision of this act that the lectures were given.

The lectures had three distinct advantages

A—To the community

B—To the physicians as a group

C—To the physician as an individual

A-1 The fact that the Sheppard Towner Act has been passed is evidence of the public confidence in this type of endeavor

2 The public gains increased confidence in the physicians when it has knowledge that as a group they are trying to better themselves by bringing the best of the profession to lecture to them

3 The public has a right to expect that physicians will keep up to date. These post graduate courses are evidence of the physicians desire to do so

B—The physicians as a group are helped

1 There is great emotional value in bringing a great group of physicians together. College days are renewed. The relation of teacher to student is re-established and especially among the older men these lectures awaken bygone memories which they have treasured

2 The lectures, through the fact that they are largely attended, developed a class consciousness in physicians. While physicians have always been strong individualists, they have many times missed the value of mass action. Any group bringing them all together under such auspices is a good thing

3 In exact proportion as trips to Vienna, Paris and London help the individual and give his patients more confidence in his work, so do these local courses make the work of the practitioner easier

4 There is a spirit of comradeship developed among the various groups in the city. The

largest membership was two hundred and two. The average for the first week was one hundred and thirty-eight, and one hundred and eleven for the second week. In Geneva the course of lectures previously given averaged an attendance of thirty-eight. This was considered very good. Wayne County had the best attendance. There was seventeen members out of thirty-six. Ontario averaged fourteen. Yates seven.

5 The plan of inviting only outstanding practitioners and teachers is a good one, for it brings to the medical men only physicians who have had a large experience and who actually know how to teach. There was not too much speculation in theory, but a thorough explanation of practical problems with their solution.

C—The physician as an individual gains through increased knowledge. The subject was of interest to every practicing physician. Twenty-five letters were written to representative physicians in Rochester. Without exception there was no criticism. On the contrary there was high praise. There was no tendency to make suggestions aiming to betterment, for everyone seemed to think that they were very well as they were planned.

It is of course impossible to bring such a large number of physicians together under such able professional tutelage and not derive great benefit. With one exception the lectures were very well given, very practical, and carried an important amount of knowledge to the physicians.

By and large these were the most largely attended medical meetings ever given in Rochester. The whole occasion seemed to be full of interest, and all in all the members of our Society felt in Rochester that they were entering a new epoch of usefulness to the members.

DISCUSSION

Dr George M Fisher, President of the Medical Society of the State of New York, spoke of a practical way of arranging a course of instruction for a county society. He said that a plan that had worked well wherever it was tried was that the Secretary of the County Society should send a questionnaire to the members asking them to indicate their first, second and third choices of subjects, and then to adopt the subject that was named by the greatest number. The State Committee on Education would provide the instructors.

POSTGRADUATE EDUCATION*

By H J NOERLING, MD, VALATIE, N Y

THIS must of necessity be termed that knowledge striven for and acquired following graduation from a medical school, where only the foundation of medical learning can be laid

With the rapidly striding advance which medical science has been making, it must needs be a trying problem to arrange a medical curriculum which will give the student a solid working basis for his chosen profession. The present day trend toward specialism in all of the branches of medicine is rapidly advancing so that the first thought of the student upon entering college is to seek that particular branch of medicine most suitable to his own ideas, desires and capabilities. Thus we find him, after graduation, and after serving his internship, either taking a post-graduate course in some large medical centre, or allying himself with an older physician doing the same work toward which his ambitions trend. What is the result? Keeping the physicians grouped in medical and civic centres where access to laboratories and hospitals is obtained, and few if any settling in outlying sections where "the old country doctor" is fast waning in age and numbers, and where his associations and activities must soon be but a thought of the past in the minds of all except those who have grown old with him and must soon follow him into the great "beyond."

If I may speak of one who was perhaps known to many here, either personally or thru patients referred to him, I can render a fitting tribute to the memory of one of our profession, a member of long standing in my own County Society, who has stood out as a remarkable example of the "old country doctor" unselfish in rendering aid professionally and financially, often cheering the holiday season of the poor by gifts to the children, food and clothing to the family, spending night after night on his rounds winter and summer, getting cat naps between calls either in sleigh or buggy or later in his auto, serving rich and poor alike, often doing his own surgery (some of it major) back in the hills by lamplight, understanding the mental and spiritual as well as the physical ailments of his patient, fearless in his work when he knew he was right, and withal finding time for study and advancement, I refer to the late Dr I C Washburn with whom I was most intimately and thankfully associated during the last few years of his life. When at his bier, I watched the line (passing by for over an hour) getting one final look at his remains,

ages ranging past eighty years, crippled with rheumatism, failing eyesight, some on canes and crutches, children and children's children whom he had ushered into the world, lawyer, banker, tradesman, clergyman, physician with whom he had associated, I couldn't help but wonder if our present-day advance in medicine must trample this type of man into the dust and have arise out of it the more modern, calculating, scientific type depending too much upon the modern appliances, hospitals and laboratories, losing that closer, friendlier and sympathetic bond which should exist between patient and practitioner.

I trust that in my zeal, I may not be misunderstood, rather I want to awaken that interest in the need of better or rather more adequate medical service to the rural communities, so that men answering the call to this type of work may not feel that they are shut off from medical advancement and may have just as good as their city brothers through some form of continued medical education.

In contrast to my past remarks, may I cite an incident in my own experience. I was considering taking into my practice a recent graduate. In discussing compensation adequate to the work required, a statement was made that owing to his more recent training, he knew a great deal more than I did, was more up to date. For a minute, I felt perhaps he was right, and yet a thought came back that I had had fifteen years of general practice and by my own efforts had kept fairly well abreast of the times with access to laboratories and visits to hospitals though perhaps not familiar with the actual technique of tests employed in laboratory diagnosis. I trust and know this feeling is not general toward rural practitioners, but it lends a possible trend of thought that medical work in rural sections becomes rutted and behind the times.

With this in mind, the first thought is that individual study and practical experience are the first steps in post-graduate education. If thirsty, man or animal seeks water to quench that thirst. So in medicine, wherever he may be, the practitioner can thirst after knowledge, and if he really wants it, can get it. A training in general practice meets all the specialties: surgery, medicine, obstetrics, skin, pediatrics, and so on thru the list. Further than that, it trains a man into a closer relation with the social, economic and mental problems of the individual, placing the doctor in the confidence of his practice. Inspiring confidence, belief in the doctor's ability to correct the ailing body, must be an essential part of perfect understanding between the

* Read at the Third District Branch Meeting, at Albany N Y, September 25 1926

sick and the medical profession, a feeling even seen when dealing with children. The general practitioner need not fall into a rut allowing the advance *ideas of medicine* to pass ahead of him. There are at his hand too many opportunities for help, periodicals, books, health courses, medical society meetings, hospitals, clinics and so on.

This brings the second thought that, following personal experience, he may gain knowledge through the experiences of others.

1 Reference library. This should be a part of every man's office equipment, books written upon the experiences of men well up in their individual specialty whose authority is fully recognized by the medical profession as a whole. But here, these books should be of a clear, concise and not too technical type, easily referred to and understandable to the average man.

2 Through weekly and monthly medical journals, digests of newer ideas advanced before incorporation into reference books.

3 Thru health courses offered by the State Departments of Health reviewing and criticizing work accomplished in preventive medicine.

4 Through attendance at State and County Medical Societies where there is always something new or unfamiliar brought to attention.

5 Through so called clinical clubs where certain groups gather socially and to relate and criticize individual mistakes and unusual cases.

6 Through special courses of lectures and dispensary work in local or special teaching centres.

I believe the medical schools should make an effort to lay the foundation of our medical education one for general practice rather than along scientific lines, real practical diagnosis and to the point, thrusting upon the student the responsibility of seeking his own specialty after graduation, allowing him to qualify as a specialist after a certain prescribed course of study. Apprentice him to one or two years with a general practitioner after leaving his internship, cutting down the premedical requirements. In this way, the older man's brain is dusted by the training of the younger man and the younger man becomes more closely associated with the actual practice of medicine.

For the general practitioner provide certain courses of study or lectures, not too burdensome as to time required, bringing out the important advances and changes in ideas proven during the year. At this point (not using this opportunity for any advertising),

I want to bring Tice's Practice of Medicine to your attention. Many may be familiar with this work. It is a loose leaf system of volumes, kept up to date yearly by the publisher, renewing old pages with the latest changes, also a monthly digest of all the International Journals, and finally a consulting bureau to whom one may send problems and receive copies of recent articles referring to the particular subject desired, placing before one the latest accepted and unaccepted medical ideas, a work for which as a general practitioner I have been craving for some time, often finding my bound volumes too burdensome to study.

During the past year, the New York State Department of Health in conjunction with the State Medical Society, offered each County Society a series of lectures by men thoroughly conversant with their individual work. This is a good start, though I believe I am safe in saying that the work was not enthusiastically taken up throughout the State. In Columbia County, those who were able to attend all or even part of this course certainly enjoyed every bit of it and hope for a continuation.

This is a step along lines carried out in other countries. Before the war, Germany offered so called "vacation courses" of four weeks duration twice a year in Berlin, dealing with practical problems for the general practitioner. Similar courses were conducted in Paris. England has the "Fellowship of Medicine and Post-graduate Association," a member paying a fee, entitling attendance at lectures given by specialists. In Canada, post-graduate courses are offered in two ways.

1 Courses conducted within teaching centres, some leading to a degree, others providing development toward specialism.

2 Extension lectures similar to the course of lectures in New York State.

In conclusion may I summarize.

American Medicine must advance to and beyond the plane set by the Old World countries. We should have the best possible post-graduate opportunities for our own men. Give the student a common sense, practical foundation in college, offering special study afterwards for the attainment of specialism. Apprentice the *new men* to general practice similar to requiring a hospital internship.

Provide adequate and interesting courses of study yearly for the general practitioner which will either coax him in or make it compulsory for him to freshen up his medical knowledge.

Preserve the good old name "Doctor," inspiring and educating the public to cooperate with him in conserving health for in the conservation of health must indeed lie the strength and wealth of our own Great Nation.

AUBURN'S EXPERIENCE WITH TOXIN-ANTITOXIN

By GEORGE C SINCERBEAUX, AUBURN, N Y

A report given at the annual meeting of the Seventh District Branch of the Medical Society of the State of New York held in Geneva, on September 29, 1926

THIS report of our experience with toxin-antitoxin in the City of Auburn, was written from the standpoint of the general physician. The immunizations were begun in 1922, when the work, at least outside of the big centers, was in its infancy, and it was no small task to sell it to the medical men and the public as well.

The use of Toxin-Antitoxin was recommended by Von Behring in 1913 and was first carried out extensively by Park and Zingher in New York. Dr. Sears, the District State Health Officer, thoroughly believing in this prevention of diphtheria and with the State of New York Health Department ready to help demonstrate its efficacy, selected Auburn for its trial, first because of the considerable number of cases of diphtheria which persisted in spite of the ordinary measures for its suppression, second, because of its size (a third class city), and third, because of the variety of its industries and its diversity of nationalities and home conditions. We had a school population of over 7,000.

The first problem was to sell the idea to the physicians, and then to the public. This was done through the city and county medical society in order to enlist the interest of the doctors. The people were reached through a public meeting at which Dr. Zingher of New York told of the work done there. It goes without saying that the physicians of Auburn were solidly behind the project.

After the preliminary interest was secured, Dr. Sears, backed by the medical men, went to work on what seemed to be a thankless job. A great deal of publicity was given to it through the papers and in meetings where it was possible. Every child, first in the public school and then in parochial schools, was listed, and cards were sent to each parent who had a child in school, for consent to be Schicked and immunized. The result was that 58 per cent of the pupils in the schools were allowed to be tested.

To give you an idea of the prevalence of diphtheria in Auburn, I will give you the number of cases by years previous to this time, so that you may more accurately see the need of this work.

Year	No of Cases	Deaths
1915	55	6
1916	39	7
1917	49	9
1918	32	7
1919	54	6
1920	90	19
1921	131	13

By these figures you can see there was a real problem of life and health, to say nothing of the

amount of time lost in school. The work of Schicking and immunizing was begun in February, 1922, and over 50 per cent of the children were Schicked and 90 per cent showing positive reactions were immunized. If by taking the 40 per cent, or over which were not tested or immunized as a control, striking results may be shown. In those cases not immunized there were 80 cases of diphtheria with 13 deaths in that year, while in the negative to the Schick test, or immunized, there were 5 cases of diphtheria diagnosed clinically and by the laboratory, out of which 4 were later proven to be Vincent's angina in diphtheria carriers. The other one occurred in a child too soon to have obtained his immunity.

Campaigns have been carried on each year since that time until the percentage of immunized children in the school is over 85 per cent with these results:

Year	No of Cases	Deaths
1922	98	15
1923	43	7
1924	22	1
1925	18	0
1926	6	0

The last death from diphtheria was in March 1924. In the six cases so far this year, none had been immunized.

Our first question in seeing a red throat or one which has the spotted throat of a follicular tonsillitis is, have they been immunized? and, if they have while we take cultures to play safe, we do not feel they are going to have diphtheria—still we play safe and take cultures.

I remember a case of one of my own patients, a boy of 8 years, who had been immunized a year before. Six months later he was Schicked but was positive. His throat was red and had some follicles present. A culture was taken and was positive, but yet he never developed diphtheria clinically. This was a case of a diphtheria carrier on a follicular tonsillitis. His Schick test taken later was shown to be negative, one year after immunization. It would seem that he would have developed a diphtheria with the condition of his throat had he not been immune.

Our work now is with the pre-school children. If we can keep them immunized, the problem has been solved, but we must keep everlastingly at it. If we do not, in a few years there will be the same problem again.

It was not so long ago that every child was obliged to be vaccinated before entering school, or at least high school. Yet today in spite of the fact that we are supposed to be an enlightened nation, we stood third among the nations as

having the largest number of cases of smallpox

The public opinion in Auburn, and I suppose in other cities, is a great deal different from what it was in 1922. Today parents are bringing their children to us and asking us to immunize them, but it is up to us doctors to keep up the enthusiasm. In regard to Schicking all cases, there is a tendency not to Schick children under seven years of age, or some say ten, before immunizing. Park says it may be omitted before immunization, first, because two-thirds of the children will require immunization in any case, second, because it is uncertain whether a negative Schick reaction is the result of transient immunity transmitted from the mother, or is produced. It has been found that in Polish or Italian children the percentage of positive reactions is much less than in English speaking children. In Auburn, Polish children showed 26 per cent positive, Italian children 36 per cent, while the English speaking about 82 per cent. This would indicate that it would save a lot of toxin-antitoxin if the foreign children were Schicked before immunization.

All children should be re-Schicked in from six to twelve months after immunization. Reviewing some of the cases here who did not show immunity until one year, it would seem that the one year interval would be the safer. I cannot give you the number of cases that were re-immunized. Among the first number immunized, 80 per cent were negative to the Schick, 319 were given the second immunization dose, and 174 were re-Schicked and 5 were found positive, 3 of whom were given a third immunization dose and all were negative.

In all the number of cases Schicked, or immunized, there was not a single severe reaction or infection.

From the results of what we have done in Auburn, we concluded first, that diphtheria is preventable, second, that immunizations can be done safely, third, that it is important to keep the pre-school child immunized, fourth, that Schicking may be omitted in young children of English speaking parents, but should always be done after immunization.

DISCUSSION

Following the paper of Dr. Sincerbeaux, there was a general discussion consisting largely of questions and answers, regarding points of which a general practitioner would wish to be informed.

1 At what age should the toxin-antitoxin immunization be given?

Ans It can be given at any age. Park had given it to 2,000 three-day old babies with no bad effect whatever. Babies develop immunity more rapidly than older children or adults.

2 Is there any danger following the injections of toxin-antitoxin?

Ans The source of possible danger would be

1, the toxin in the mixture, and 2, the horse serum which contains the antitoxin. The dose of toxin is now so extremely small that it does not produce even a soreness at the place of injection. Where formerly slight soreness developed, the reduced amount of toxin now given does not produce even a transient soreness.

As to the possible danger from the antitoxin that is given, the dosage is that which would be given to desensitize a susceptible patient. It is safe even if the patient should be sensitive to horse serum. Moreover, giving an immunizing dose may forestall the necessity of giving a large dose of antitoxin later in life.

3 The Schick test, shall it be used as a routine measure?

Ans Most children under the age of ten will give a positive Schick test, and so the standard practice is to give the toxin-antitoxin in all children below the high school. However, when the Schick test is given three months after the toxin-antitoxin, it will reveal those (about 5 per cent) who fail to produce antitoxin and who therefore need a second dose.

4 Is this Schick test dangerous?

Ans Never.

5 Who should give toxin-antitoxin?

Ans The only persons who can give it are physicians. Nurses and laboratory workers cannot give it legally.

6 How long does immunity last after toxin-antitoxin?

Ans The toxin-antitoxin has been given for only ten or twelve years, but immunity lasts for that length of time. The group showing the greatest death rate is that of children under five years of age, and the next group is that of school children. If the immunity lasts for only a few years, the children who are immunized will be protected during the years when they are most exposed to the diphtheria.

7 What is the duty of a physician in giving it to his private patients?

Ans It is entirely ethical for a physician to offer to give the immunizations to the children of his families, and to seek to educate the parents as to its benefits. Moreover the feeling is growing among physicians that liability may lie in a failure to give toxin-antitoxin.

8 What are the relative duties of lay organizations and physicians in regard to toxin-antitoxin?

Ans Individual physicians are to give toxin-antitoxin to those who need it to encourage parents to use it on children, and to cooperate with the school authorities in immunizing the pupils of public schools. Lay organizations and boards of health are to conduct educational campaigns in order to instruct people regarding toxin-antitoxin and to persuade them to permit its use.

PUBLIC HEALTH ACTIVITIES IN THE COUNTY MEDICAL SOCIETIES OF THE FOURTH DISTRICT BRANCH

By E HARRISON ORMSBY, M D, AMSTERDAM, N Y

A report given at the annual meeting of the Fourth District Branch of the Medical Society of the State of New York, held in Plattsburg, October 1, 1926

AS the family in the home is the unit of civilization, so is the county society the unit of organized medicine. As the home is the place where is laid the foundation for teaching religion, morals and education, so is the county society the place from which knowledge of health and disease should be distributed to the great group of family doctors. Evolution in medicine progresses rapidly from one major discovery to another, as the tireless and relentless research workers bring to us each year their increasing discoveries from the laboratory, the hospital, and the college, and deposit them in the laps of our several county, district, state and national societies for distribution and application. A great function of a county medical society is that of distributing knowledge to its members by some organized system such as the graduate courses promoted by the Medical Society of the State of New York. At present preventive medicine is being emphasized by thoughtful leaders in medical societies, and the movement is as important as any of the past medical achievements. To rid civilization of the dire results of bacterial, mechanical, thermal, or chemical invasion by prevention is the simplest and easiest way to promote health and prolong life that can be found. This must be done by organization and practical education and is best accomplished by perseverance in work and effort. The organization best adapted to do this work is the county society. The favorable response of the county medical societies is demonstrated by the prominent place given to preventive medicine in the programs of the meetings of the District Branches. On every such program we find papers dealing with public health problems that are real live, up-to-the-minute, worthwhile issues. Every county society throughout the State seems to have entered this new field, with some branch of it peculiarly and particularly adapted to its community needs singled out for ultimate solution and consummation. Our own district composed of eleven counties in the State has been no laggard.

For a long time physicians have been wagged too much like the proverbial dog's tail by all sorts and kinds of lay societies and organizations who, through the press and monthly publications, and by weekly runs and one night stands, attempt to establish in the public mind the standard of right and wrong in the physical field. It is now high time for doctors to take their light out from under the bushel and let

it shine forth so that their good works may be seen.

Dr George M Fisher, President of our State Society has said that there is an obvious increase of interest on the part of the public in the prevention of disease as manifested by the increasing number of agencies with programs calling for education of the public, and the completion of these programs calls for assistance from the trained physician, and we must be prepared to meet the demand. How true this is! But I will go a step farther and say that we should be the inspiration for these organization, and that we should lay out their programs, and that we should lead all the way.

To accomplish this purpose of leadership we must organize our society in such a way as to stimulate each individual member to give to the organization the best there is in him. This stimulation comes about by interesting each member and can be arrived at through post graduate education on modern subjects, by means of courses designed for real hard study. Such a course was put on by our society last spring and for a full report of it I refer you to the NEW YORK STATE JOURNAL OF MEDICINE, vol 26, No 16, p 725, dated August 15, 1926, and I urge all of you if you have not already done so to read this account.

The subject chosen for a course in graduate medical study should be live and modern, and suited to the particular community in which it is given. Such a course will interest, stimulate, educate, and enlighten the individual member. After he has become interested and educated, he will be ready to spread the news by both word and deed. This news, as concerns the public, is along the lines of public health and so a public health committee is necessary in the county society and should consist of all the members in the society engaged in public health work, especially health officers. The chairman of the committee in Montgomery County is a District State Health officer, and our committee numbers ten. There is no limit then to the scope of work available, or the men to further it. Sub-committees can be appointed to take charge of such activities and so-called campaigns as periodic health examinations, better milk and water supplies, diphtheria prevention or toxin anti-toxin campaigns, tuberculosis prevention, venereal disease prevention, child welfare and prenatal work, school medical inspection, smallpox vaccination, typhoid inoculation, cancer prevention, clinics for children of pre-school age, and

anything and everything else pertaining to the elimination of disease and promotion of better health. Several of these activities can be combined, and such combinations will save time and money. Let us take, for instance, the clinics for examination of children of pre-school age. Montgomery County has taken this as another of its public health activities for this year. The clinics are organized as follows:

The committee or its designated representative visits the political head of a community—mayor of the city, president of the village, or supervisor of the town, and explains what the county society is striving for and asks for an allowance in the budget to defray necessary expenses. Having obtained this, the health officer of the community concerned designates a clinic date, one in the spring and another in the fall. Prior to the time for the clinic to be held, the public health nurses are sent out to canvass and make personal interviews at homes where children of pre-school age are located and solicit attendance at the clinic. Some member of the society from a distant part of the country, and designated by the public health committee, arrives at the proper time and conducts the clinic. He examines the children for remedial physical defects, and records his findings, together with recommendations on an individual card kept for the purpose, and the information is conveyed to the family physician where one is specified, otherwise to the family. At the same time these physical examinations are made, the first dose of toxin-antitoxin, or typhoid inoculation is given, or vaccination against smallpox performed. The later inoculations or vaccinations can be given by the family physician or health officer. Such a procedure is being successfully operated in our county and it can be worked out in any and all counties equally well. All other public health activities can be handled in similar manner and by so doing the county society becomes the real leader in public health in its own community, setting aside the fear or threat of State medicine, putting to rout all the quacks, educating and enlightening its own people in a practical and scientific way, and making itself the real authority and power in all matters of health in the community.

While I will not go into detail concerning the activities of all of the county societies in the district, I will outline their important ones and suggest that at the proper time representatives from each society tell us more in detail concerning these.

Every county society in this district has adopted the diphtheria prevention campaign,

so that this disease should soon pass from our midst.

Post-graduate courses have been conducted in Clinton, Fulton, St. Lawrence, Warren, and Washington Counties, as well as Montgomery.

Public health clinics and tuberculosis camp have been among the particular aims of Washington.

Saratoga is dealing with periodic health examinations.

Essex has a charity program.

Clinton and Essex Counties have joint committees working with the board of supervisors and public health agencies, and all the county societies are alive to the importance of this new era in medical leadership.

DISCUSSION

Dr. S. W. Sayer of Gouverneur, District State Health Officer, described the child welfare work that was done in St. Lawrence County under the leadership and direction of the St. Lawrence County Medical Society. At the conclusion of the pediatric course that was described in this JOURNAL for August, 1925, page 876, the County Medical Society planned a series of clinics for the examination of babies who were presumably well. A special committee of the County Medical Society chose the places for holding the clinics and appointed local men to make the examinations. Each examining physician was paid fifteen dollars for each clinic by the State Department of Health and out of the Sheppard Towner fund. The committee required every examining doctor to be a member of the County Medical Society. Twenty-six clinics were held, each attended by over a dozen children. Over 400 children were examined. The clinics were held in the smaller places where doctors were few and local facilities were lacking. The local physicians took great interest in the work. Several bought books on pediatrics as the result of the clinics, and six doctors joined the County Medical Society in order to share in the experience of examining the children. The work was a great success and will be continued.

Dr. William Munson, District State Health Officer, spoke of the activities of the representatives of the State Department of Health in going among the practicing physicians and explaining the details of the methods of giving immunizations and of securing publicity for public health campaigns, so that the physicians will find the people and members of boards of health receptive to the suggestions of the medical men. He said that intimate contact with physicians was necessary in order to do practical preventive work along any line.

THE PERIODIC HEALTH EXAMINATION

By EARL H. KING, M.D., SARATOGA SPRINGS, N. Y.

Abstract of a talk given before the Fourth District Branch of the Medical Society of the State of New York at Plattsburg, N. Y., October 1, 1926

THE object of this talk is to present an appeal for a more general and systematic adoption of the Periodic Health Examination as a part of the routine work of the family doctor. Much has been said about "Preventive Medicine" as applied to communicable diseases, and every physician realizes his duty in that line. But the diseases which are susceptible to modern prevention include those of the heart, kidneys, intestines, joints, and in fact of nearly all the other organs. It is not possible to foresee and prevent all diseases, but there are so many that are detectable and preventable that a family doctor is justified in urging his patients to undergo periodic health examinations. Patients consult a doctor in order to get an answer to one of three questions:

1. Have I a disease?
2. Have I a tendency to a disease?
3. How may I acquire positive health?

The booklet on "The Periodic Health Examination," issued by the Medical Society of the County of New York, in 1925, emphasizes the preclinical signs of disease, and describes those conditions which are suggestive to the examiner, and lead him to make a detailed examination along certain lines. Tuberculosis and cancer are two well-known examples of diseases in which preclinical signs are usually present at a stage sufficiently early to enable the doctor to give effective treatment.

What is a health examination? It is no mere cursory glance at the patient, nor is it a judgment based on long acquaintance, for when a patient himself is unaware of incapacity or danger, much less will his friends or his doctor suspect danger.

A doctor making a health examination will consciously have in mind at least eight conditions:

1. A blank to guide him in making the examination. There is the blank got out by the American Medical Association, the one by the New York County Medical Society, and that by the Kings County Society, and there are several others developed by the medical organizations of New York State. A doctor needs a blank in order to make his examinations uniform, and for recording his findings.

2. An inquiry into the health habits of the patient in his home, his business and his recreational hours.

3. The patient's mental attitude toward himself, his family, his neighbors, and toward life in general.

4. His family history, not in too great detail, but sufficiently to throw light on general tendencies, such as tuberculosis, and "Nervousness."

5. A history of previous diseases and accidents.

6. Subjective symptoms, or what the patient himself thinks is wrong with himself or a digression from an absolutely normal condition.

7. A complete physical examination, including the neurological.

8. Advice regarding treatment. To the patient this is the most important part of the whole examination, and on it will depend its success or failure. The family doctor is in the best possible position to give the advice in such a form that it will be heeded.

Remember that a great responsibility rests upon the examiner. The patient puts himself in the doctor's hands for diagnosis and treatment in order that he may avoid future trouble. He expects advice regarding his diet, mode of living, sleeping, recreation and the other conditions which may affect his future health, and he rightfully expects that the remedy shall not be worse than the disease. A patient has his living to make, and he lives in a world full of beauty to be enjoyed. A nice balance of warning and reassurance is always difficult to maintain in giving advice.

How much skill is required to make a periodic examination? Just as much as a studious family doctor is expected to have. The average physician should be able to detect the preclinical signs and symptoms that point to the necessity of an examination by a specialist, or a laboratory procedure.

How shall the desire for periodic examinations be aroused?

The doctor must be reached through his medical societies. A movement sponsored by the leaders of a county medical society will speed up the acquisition of both knowledge and desire on the part of the individual doctors. The local doctors themselves know how to arouse interest in the work.

The local hospital is the natural health center of a community, and the natural center from which health examinations may be promoted.

Submitting to an examination himself is one of the most efficient of all means of arousing the interest of the doctor and stimulating his desire to acquire knowledge. Putting himself in the patient's place, literally and completely, will be his best training in methods of dealing with his patients. Moreover, it will prove his sincerity in what he urges his health client to do.

The time is ripe for every County Medical Society to begin an active campaign for its members to make health examinations of persons who are apparently well.

anything and everything else pertaining to the elimination of disease and promotion of better health. Several of these activities can be combined, and such combinations will save time and money. Let us take, for instance, the clinics for examination of children of pre-school age. Montgomery County has taken this as another of its public health activities for this year. The clinics are organized as follows:

The committee or its designated representative visits the political head of a community—mayor of the city, president of the village, or supervisor of the town, and explains what the county society is striving for and asks for an allowance in the budget to defray necessary expenses. Having obtained this the health officer of the community concerned designates a clinic date, one in the spring and another in the fall. Prior to the time for the clinic to be held the public health nurses are sent out to canvass and make personal interviews at homes where children of pre-school age are located and solicit attendance at the clinic. Some member of the society from a distant part of the country, and designated by the public health committee, arrives at the proper time and conducts the clinic. He examines the children for remedial physical defects, and records his findings, together with recommendations on an individual card kept for the purpose, and the information is conveyed to the family physician where one is specified, otherwise to the family. At the same time these physical examinations are made, the first dose of toxin-antitoxin, or typhoid inoculation is given, or vaccination against smallpox performed. The later inoculations or vaccinations can be given by the family physician or health officer. Such a procedure is being successfully operated in our county and it can be worked out in any and all counties equally well. All other public health activities can be handled in similar manner and by so doing the county society becomes the real leader in public health in its own community, setting aside the fear or threat of State medicine, putting to rout all the quacks, educating and enlightening its own people in a practical and scientific way, and making itself the real authority and power in all matters of health in the community.

While I will not go into detail concerning the activities of all of the county societies in the district, I will outline their important ones and suggest that at the proper time representatives from each society tell us more in detail concerning these.

Every county society in this district has adopted the diphtheria prevention campaign,

so that this disease should soon pass from our midst.

Post-graduate courses have been conducted in Clinton, Fulton, St. Lawrence, Warren, and Washington Counties, as well as Montgomery.

Public health clinics and tuberculosis camp have been among the particular aims of Washington.

Saratoga is dealing with periodic health examinations.

Essex has a charity program.

Clinton and Essex Counties have joint committees working with the board of supervisors and public health agencies, and all the county societies are alive to the importance of this new era in medical leadership.

DISCUSSION

Dr. S. W. Sayer of Gouverneur, District State Health Officer, described the child welfare work that was done in St. Lawrence County under the leadership and direction of the St. Lawrence County Medical Society. At the conclusion of the pediatric course that was described in this JOURNAL for August, 1925, page 876, the County Medical Society planned a series of clinics for the examination of babies who were presumably well. A special committee of the County Medical Society chose the places for holding the clinics and appointed local men to make the examinations. Each examining physician was paid fifteen dollars for each clinic by the State Department of Health and out of the Sheppard Towner fund. The committee required every examining doctor to be a member of the County Medical Society. Twenty-six clinics were held, each attended by over a dozen children. Over 400 children were examined. The clinics were held in the smaller places where doctors were few and local facilities were lacking. The local physicians took great interest in the work. Several bought books on pediatrics as the result of the clinics, and six doctors joined the County Medical Society in order to share in the experience of examining the children. The work was a great success and will be continued.

Dr. William Munson, District State Health Officer, spoke of the activities of the representatives of the State Department of Health in going among the practicing physicians and explaining the details of the methods of giving immunizations and of securing publicity for public health campaigns, so that the physicians will find the people and members of boards of health receptive to the suggestions of the medical men. He said that intimate contact with physicians was necessary in order to do practical preventive work along any line.

THE TRINITY OF HEALTH ORGANIZATIONS

The principles of the efficient interrelationship of the three groups of health organizations—physicians, departments of health, and lay societies—were set forth in an editorial in this JOURNAL in the issue of January, 1926. The same principles are stated in an official way in a report of a special committee to the directors of the Canadian Medical Association as recorded in the *Canadian Medical Association Journal* of September, 1926. The essential part of the report takes the form of seven propositions, as follows:

"1 That the interrelations of the Medical Profession (as a whole) with the public (as a whole) may be divided for convenience into three natural groups of activities—therapeutics, prevention of disease, promotion of health

"2 That the first group of activities, therapeutics, is by general understanding and consent the field of the practicing medical man. Here is included all diagnosis and treatment of the sick, sick clinics, dispensaries, etc.

"3 That the second group of activities, prevention of disease, is by general understanding and consent the field of the governmental (including municipal) public health bodies. Here is included all diagnosis, isolation, quarantine, and other services (except therapeutic service to the sick) which may prevent disease, and emergency preventive medicine.

"4 That the third group of activities, promotion of health, concerning the allocation of which confusion and doubt exists in many quarters, should be considered to include all medical, surgical, or nursing services (exclusive of therapeutic services to the sick) which are extended to the presumably well, including prenatal clinics, well-baby clinics, medical school inspection, periodic annual examinations, etc., whether these be for the preservation of existing health, or the discovery of unsuspected and incipient disease, also all advice growing out of such examinations, and all preventive medical, surgical, or nursing procedures which may be employed to fortify the body against future disease (preventive medicine proper).

"5 That already existing organizations, governmental or otherwise, already engaged in promotion of health as above defined, be approved and supported in so far as their activities conform with this definition.

"6 That organizations hereafter formed for the promotion of health as above defined, wherever agreeing with the above approved

outline, be actively organized by local medical associations, advised and guided, for the sake of uniformity in policy and procedure, by the provincial medical associations, and the provincial departments of health.

"7 That such local medical associations shall act always in cooperation with a well organized lay association or combination of lay associations, preferably possessing provincial or national affiliations, the lay organizations to provide all finances, and all organizations other than medical, surgical, or nursing, but all medical, surgical, or nursing professional service to be organized and conducted by the respective professional bodies."

The report suggests that the Canadian Medical Association, representing the doctors in private practice, and the Canadian Public Health Association, representing official departments of health, agree on these principles, and then present them to the great national lay public health societies for their endorsement. "Once this is done," continues the report, "then let the Canadian Medical Association in national affairs, each provincial society in its own jurisdiction, consider carefully and act energetically, efficiently, and progressively, in specific and definite ways, suitable to the local conditions, in aid of the public welfare, thus furnishing to modern public health that direct advance from the medical profession and by the medical profession which in the past has been conspicuously lacking."

"The medical profession as a whole has always performed finely and well in therapeutic services to the sick, the call now is to furnish parallel service to the well."

The Medical Society of the State of New York and its component District Branches and County Societies, have acted on these principles, although they have never formulated them in an official manner.

While the physicians of the United States are closely bound together in their county, state, and national societies, the workers in departments of health are not so completely organized unless the American Public Health Association may be considered to represent them. When it comes to the lay societies, there is still less of a cohesive union, although the National Health Council is the result of an attempt at coordination. But whether or not the principles are formulated in words, the physicians of New York accept their spirit, and are already asserting an increasing leadership in the necessary fields of preventive and promotive medicine.

REVELATIONS OF THE DISTRICT BRANCH MEETINGS

The meetings of the District Branches have demonstrated the quiet solution of the old problem of how to arouse an interest in county medical societies. The part of every program that has aroused the greatest interest has been the recital of spontaneous activities along civic lines, particularly the anti-diphtheria campaign, graduate education, and periodic health examinations. These newer activities have not come from the application of a uniform plan of action devised by a few leaders in a cloister, but they have been developed along individual lines by the members in the field according to the needs of the local communities.

These activities constitute real progress of a permanent nature, and the result justifies the oft repeated policy of the leaders of the State Medical Society—that doctors can control the public health work of a community. What has been lacking in the past has been the inspiration that comes from personal contact with the representatives of the central office of the State Society and that has been supplied by visits of the President, the Secretary, and the Executive Officer, and the intimate contacts that have been the results of the graduate courses. The county medical societies are live organizations that are benefiting both their members and the public.

MEDICAL PROGRESS

Coronaritis and Embolic Subendocardiac Infarction—R. Lutembacher relates two cases of his disease association but makes very few comments beyond the statement that it is of common occurrence as a complication of arterial myocarditis and valvular cardiopathy (*Archives des maladies du coeur*, August, 1926). The first case was largely made up of the autopsy finds while the second was better represented from the clinical side. This patient was a man of 43 with decompensation of the left ventricle. He applied for treatment for nocturnal dyspnea and received injections of ouabain with striking disappearance of the symptom. Since Wassermann was strongly positive the patient was given a course of injections of mercuric cyanide. He afterwards disappeared from the clinic but returned some months later with violent dyspnea and edema of the lungs. The left ventricle was greatly augmented in volume and but a slight response followed venesection and ouabain injections. A crisis of acute insufficiency now appeared with general anasarca and fall of blood pressure. Ascites occurred to the extent that tapping became necessary. Death took place after pericardial friction sounds and a purpuric outbreak had developed. Autopsy showed evidence of infarction from emboli in the kidneys and spleen with purpuric areas in the pericardium and intestine. The source of the emboli was a small thrombus attached to the posterior wall of the left ventricle apparently secondary to a process in the myocardium opposite the area. The microscope showed a sclerosis of the entire thickness of the myocardium but without any thinning of the ventricle wall. Coronaritis was also present with narrowing of the caliber of the vessels. The left ventricle was hypertrophied and dilated with intact valves, although the patient had presented a systolic mitral murmur.

Angina Minor—A full-blown attack of angina pectoris cannot fail of recognition by the physician or the patient, but the milder forms which have been called larval, or the "petit mal" of angina, may escape recognition unless one has the possibility of their occurrence in mind. In a lecture delivered before the British Medical Association at its meeting in Hastings in June of this year (*British Medical Journal*, July 10, 1926), John Hay calls attention to this minor form of angina and reviews its symptoms and treatment. The symptoms, like those of angina major, result from cardiovascular inadequacy. The most common is substernal discomfort or pain on exertion or exposure

to cold, it is variously described by the patient as a sense of oppression, tightness, or constriction, a feeling of weight or one of emptiness, and is usually regarded by him as indigestion, this opinion being strengthened by the fact that exercise immediately after a meal is quite likely to bring on an attack. In the early stages dyspnea may follow this discomfort if the effort is continued, but later the shortness of breath is the first manifestation, pain coming only if the effort is persisted in. The exciting causes of an attack of angina, whether major or minor, namely effort and exposure to cold and sometimes excitement, have a common characteristic in that they are such as to bring about a rapid strain on the arterial side of the circulation and especially on the left ventricle. In a large proportion of anginal patients there is either a lesion of the coronary arteries or persistent high blood pressure. In addition to the substernal discomfort there may be mild radiating pains which, when they occur, are of great assistance in diagnosis. Sometimes the pain may be erratic in character, such as a dull ache or cramp in the shoulder or arm, and this, contrary to the radiating pain, may be misleading. Another sign of diagnostic value is a vague dread or intangible foreboding, an uncanny feeling that there is something fundamentally wrong, or an apprehension which may persist even after the physical symptoms have long since disappeared.

Drumstick Fingers in Heart Disease—F. Czyhlarz, in a brief communication in the *Wiener klinische Wochenschrift*, July 22, 1926, points out that P. Marie and E. Bamberger independently reported the coincidence of clubbed fingers with thoracic disease. The mechanism was thought to be practically the same whether the heart or lung was diseased—cyanotic condition of the terminal phalanges whether from cardiac insufficiency or disturbance of the circulation from incessant coughing. The author would point out that cardiac decompensation is not essential in the causation of these cases for he has repeatedly seen these finger with perfectly compensated valvular lesions. In recent years Cotton has called attention to the frequent coincidence of clubbed fingers with endocarditis lenta, which is quite in accord with the author's own experience. Two aspects of the matter do not seem to have been discussed as yet, one being the increased length of the clubbed fingers while the other has to do with the coincidence of this alteration with aortic disease. In many cases a distinct elon-

case for over a year and assembled a series of ten electrocardiograms, collected at monthly intervals, which showed marked uniformity. They showed very decisively that contraction of the ventricle preceded in point of time that of the auricle. The mechanism, in the author's view, is akin to that of the Adams-Stokes syndrome. Contraction of the auricle is retarded by stenosis of the artery of the atrial bundle. In this patient the artery in question was given off from the right coronary and behaved as a right lateral auricular artery. It was given off 3 cm from the orifice of the coronary and the stenosis was found at this point. It represented a narrow defile, the result of a cuff of thickening due to endarteritis. Aside from this lesion the artery was quite normal. The two disturbances of rhythm, then, the Adams-Stokes and the inversion of the auriculo-ventricular sequence, are due to the same type of lesion respectively in the artery of the ventricular and in that of the auricular bundle.

Treatment of Bergeron's Stomatitis with Bismuth Locally—Bernardo Sampaio prefers the name of "Bergeron's stomatitis" to Vincent's fusospillary or ulceromembranous stomatitis, which is the commonly accepted term of stomatologists, this is probably because Bergeron gave a good clinical description of the malady in 1859. The author relates a case which he saw in November, 1925, in a boy of 8 years in which he found at first only some aphthous lesions which later developed into superficial ulcers on both sides of the tongue, accompanied by a horrible fetor of the breath. Similar lesions later developed on the mucosa of the lips but none are mentioned as occurring on the gums. There could be no possible doubt of the diagnosis which was of course confirmed by the microscope. The author applied soluble bismuth in liquid form as a drug of spirillocide properties, and improvement was at once apparent in the disappearance of the false membrane from the raw surfaces. The severe local pains which had greatly interfered with eating were also relieved, and the patient made a good recovery. The author gives an historical resume in which he shows that up to the time of Bergeron this condition had been confused with certain other very serious maladies comprising buccal diphtheria and noma. The French author recognized the autonomous nature of the malady, its ulceromembranous character, and its contagiousness. Nearly forty years elapsed before the actual nature of the disease was recognized by Bernheim and the role of Vincent's symbiosis understood. In conclusion the author pays a tribute to his Brazilian colleague Dr. Albernaz, who in 1922 discovered the value of bismuth in Vincent's angina.—*Brazil-Medico*, May 22, 1926.

Pathogeny of Gastroduodenal Ulcer and Its Treatment by Parathyroid Extract—E. Palier of New York refers to his already published theory that peptic ulcer is a sort of lithiasis of the mucosa of the gastroduodenal tract, in which the gastric acid in dissolving the calcium salt causes a defect in the mucosa—a place of minimum resistance. This theory, the writer believes, will be found to solve all of the riddles of this mysterious disease, and in conjunction therewith one may revive another which is quite compatible with it, the endocrine, in which while several glands may be at fault the chief should be the parathyroid which presides over the calcium metabolism. It is an interesting coincidence that several authors have praised parathyroid extract in *ulcus cruris* and certain other forms of ulceration. Grove and Vines, who have had much experience in the use of parathyroid, regard this substance or rather the calcium content of the tissues as an antiseptic and hence uphold the infectious origin of ulcers, but the present author regards the hypothesis of focal infection as a cause of peptic ulcer as quite untenable. He has sought to demonstrate this in another paper and refers for further details to an article on the cause of peptic ulcer in the *Medical Journal and Record* for June 6, 1922. The calcium theory of the author explains why the patient need not suffer from hyperchlorhydria to develop peptic ulcer for he may exceptionally have a deficit in stomach acid or even be achlorhydric and yet suffer from the malady. As for surgical treatment, Palier's, if theory holds, this should be limited to gastroenterostomy.—*Le Bulletin Médical*, July 7-10, 1926.

Colitis Ulcerosa—J. P. zum Busch, writing in the *Muenchener medizinische Wochenschrift*, June 25, 1926, gives an excellent account of this affection, which until recently has been regarded as excessively rare and as a possible variant of ordinary dysentery. He looks upon it as an affection of the type of appendicitis and duodenal ulcer, in that it was originally regarded as rare, although in reality it was only unrecognized. He recalls that as recently as 1908 his report of 16 cases of duodenal ulcer was looked on as a mistake, although today the disease is recognized as a common one. So with colitis ulcerosa, for a recent writer goes so far as to state that the recorded material is around fifty cases. The author himself has recognized 43 cases in the clinic. He finds it of the same incidence in men and women but rare in children. Among his cases there was only one young child, aged 2 years, in which the first diagnosis, not unnaturally, was intussusception. The usual beginning of the disease is insidious, an apparently simple diarrhoea. It is very exceptional for it to simulate one of the acute abdominal diseases.

gation is evident, not only of the terminal phalanx but of the other phalanges. The aortic affection in which he has seen the finger clubbing is insufficiency due originally to endocarditis, and he has not seen the clubbing in other forms of aortic disease. He associates the elongation of the fingers with the youth of the average patient with endocarditis, there being a certain growing impulse inherent in the tissues. In conclusion he would distinguish between two types of the deformity, one being due to stasis or passive congestion while the other appears to be the result of active hypere-mia, this second form being associated solely with aortic disease.

Epilepsy and Heart Disease—In connection with the report of a case of epilepsy in a woman suffering at the same time from valvular disease of the heart, R. O. Moon discusses the question of the interrelation of those two affections (*Lancet*, July 10, 1926). He admits that epilepsy and heart disease are both so common that they would naturally often be found in conjunction without there being necessarily any causal relation between them. Nevertheless, even if there is no direct causal connection between epilepsy and heart disease, it does not follow that the two diseases are uninfluenced by one another. The writer believes that epilepsy when associated with cardiac disease will exhibit certain phenomena which are not quite like those of ordinary epilepsy. Thus the classical onset of a fit with a cry, a fall, loss of consciousness, and convulsions is not common with the cardiac epileptics, whose attacks are characterized rather by giddiness, fits of absence of mind, and transient intellectual troubles—in a word, by psychic epilepsy. The aura, too, in these cardiac cases often takes the form of palpitations, precordial pain, the feeling of a wave of blood which rises up into the head and produces dizziness. As a rule, this condition lasts longer than the ordinary epileptic aura, it develops slowly, giving the patient time to sit down, and at times the aura constitutes the whole of the attack without giving rise to convulsions or loss of consciousness. The fits in cardiac cases are usually infrequent and less severe than in uncomplicated epilepsy. Some of the author's cases have exhibited circulatory disturbances as an aura, such as palpitations, feeling of numbness in the hands, severe pain in the cardiac region, pulsation of the cervical arteries, sensation of rapid beating of the heart with the face becoming hot prior to the epileptic fit. Another feature of cardiac epilepsy is that the attacks usually occur at night, this fact has been emphasized by Lemoine, who considers that in mitral cases the attacks are caused by cerebral congestion, and states that they may cease when the patient sits up in

bed, whereas in aortic cases the attacks are due to cerebral anemia and are cut short by the horizontal posture.

Influence of Pain on Blood Pressure—P. Martini and F. Graf write of the influence of painful dentistry on the normal blood tension and the tension of hypertonics, and arrive at the following conclusions. In addition to pain we must reckon the psychic element of fear and apprehension. In normal tension the increase of pressure varies with the severity of the pain and also with the excitability of the patients. If the pressure falls this fall is associated with syncopal symptoms and is seen only in certain groups as children and asthenics, however, extremely severe pain may cause a fall in the sound and non-nervous subject. In the nervous subject even painless intervention will send up the pressure, this also being evident before the actual intervention. If the test subject is a hypertonic he will also be found to be nervous and excitable in part as a symptom of his hypertonus and his reactions are those of the nervous subject, for even painless intervention will increase his pressure. The increase of pressure in some of these patients is enough to threaten death and a tabulation by the authors shows that figures like 290 and 270 may be attained. Hence the question of the advisability of giving hypotonic drugs like diuretin and papaverin which are able to relax the contracted blood vessels. The authors do not believe these to be indicated because they do not reach the psyche. Possibly the bromides will prove superior for this purpose.—*Muenchener medizinische Wochenschrift*, June 25, 1926.

Inversion of the Auriculo-Ventricular Sequence—In a paper with this title, read before the Paris Academy of Medicine (*Bulletin de l'Académie de Médecine*, June 22, 1926) E. Geraudel refers to an earlier paper on the Adams-Stokes syndrome in which he demonstrated the pathogenesis of a particular case in which was found a stenosis of the artery of the ventricular junctional bundle. This lesion was made responsible for the deficit in the work of the artery as shown by the slowing of the ventricular rhythm. At a later period he had the opportunity of studying a second case referred to him by Professor E. Widal, and here he again found the identical lesion. The present paper is devoted to another anomaly of rhythm, namely the inversion of the usual order of succession of the contraction of the different cardiac chambers, the ventricle preceding the auricle in this respect. The patient was a man of 63, an old syphilitic presenting an aortitis with a double murmur at the base. He died with all the evidences of insufficiency of the left ventricle. The author followed up this

LEGAL

By LLOYD PAUL STRYKER, Esq
Counsel, Medical Society of the State of New York

THE YEAR'S WORK BEGINS

Your counsel, with the opening of the courts on October 4th, took up again the interesting and exacting tasks committed to his charge. Refreshed from the summer's rest he is able to approach the work with renewed enthusiasm and new determination, so far as in him lies, to vindicate and uphold the standards of the medical profession and the rights of its individual members.

It was your counsel's peculiar privilege, during his vacation on the exhilarating coast of Maine, to be thrown closely in contact with three of the outstanding surgeons of this city. He could not but regret that to the laity the opportunity so seldom is accorded of making the discovery that doctors are more than mere instruments of science—that they are splendid human beings.

It is therefore with renewed zest and interest that the writer faces a calendar of upwards of three hundred cases pending in the various courts of record of this State. Many of them are difficult and exacting, all of them are important, and each of them involves the most treasured possession which the professional man can list among his assets—his good name and professional reputation. The splendid co-operation and loyal support which the members of the State Society have given counsel throughout the length and breadth of our commonwealth strengthen and reassure him in the performance of his duties.

Realizing full well, as a member of the sister profession of the law, the restrictions sedulously drawn about the great profession of the healing art, the writer nevertheless oftentimes has wished that there were some way in which the general public could be better informed, and from this could attain to a juster appreciation and appraisal of the great service to mankind that the honorable practitioners of the healing art are rendering. Your counsel's consciousness of this fact increases in proportion to his numerous and very pleasant contacts with the physicians and surgeons throughout the State.

Only a short time ago one of the writer's dearest friends was taken with an acute attack of colicistis. His case was complicated by a diabetic tendency. Appreciating of course, far less than doctors do, the dangers of these complications, your counsel was nevertheless sufficiently aware of them to entertain the gravest possible concern for his friend. How can his feeling of appreciation ever be expressed in words for the services rendered in this matter by one of the

surgeons of this city! It was not only the skill, the experience and the knowledge of the surgeon that were reassuring but the confidence that came from perfect faith in the character and the conscience of the man who was to perform the operation. Could he pull the patient through? If he could not, then there was nothing else that human power could do.

The friends and relatives, with drawn and anxious faces, assembled at the hospital in the early morning hours and there watched while the nurses prepared the patient for his journey to the operating room. The wheel chair was brought in, the patient was wrapped in shawls and placed in this conveyance for what might well be his last journey on this earth. At the elevator we said good bye. The anxious seconds dragged—a half hour went by—no report! An hour—still no news from the front! Ninety minutes! At last the sick man, still deep within his ether fumes, was returned to his room.

With perfect consciousness of the responsibilities for the human life entrusted to his care, with a skill and knowledge acquired by long and patient study, and an experience which only years dedicated to his work could bring, the surgeon had prevailed. The patient lived and has now been restored to health.

As the writer of these pages waited in that hospital he could not but reflect how inadequate is any mere financial compensation for all that the surgeon, carrying in his skilled fingers the fears and hopes of countless friends, had done to bring about a successful consummation. And yet how often has your counsel seen similar skill and competence rewarded by an unjust and mean attack upon one who has done all within his power—all that science, skill and conscience could achieve!

With all the difficulties involved in such a program, your counsel more than ever strongly wishes that in some way the lay public could be brought to a juster, fairer and more intelligent appreciation of the great work the medical profession is performing for mankind. There is a colloquial phrase whose meaning has been dulled by too-constant use: "Selling an idea to the public." This principle, alas, all too well understood and employed by quacks and the unworthy, has never been invoked by those whose just claims to confidence and respect are never voiced. All that smacks of publicity or advertising on the

If the subject is healthy at the start he may retain his health for some weeks but in time emaciation appears. Another form sets in with fever of an intermittent type. After large ulcers form and become infected we see a late type of fever of septic nature. The course is very uncertain and death may take place at an early period, perforative peritonitis being a common complication. The prognosis is grave—about 50 per cent perish. The diagnosis may be made early through the use of the sigmoidoscope by means of which the ulcers may be seen in their small superficial stage. Autopsy shows every degree and stage of the ulcerous process and in those uncomplicated cases in which death supervenes in a few days the entire colon is deprived of its mucosa, as if shaved off with a razor. The author found not the slightest evidence of a dysenteric element in any of his 43 cases. There is nothing new under the head of treatment. Sixteen patients were greatly relieved by an artificial fecal fistula.

Treatment of Pernicious Anemia with Arsphenamine—In an article in the *Deutsche medizinische Wochenschrift* of June 18, 1926, E. Hartmann of Professor Minkowski's Breslau clinic, calls attention to the lack of finality in the treatment of this affection, for of the many plans in use none is more than a partial success. When improvement results there is always the possibility that a spontaneous remission has occurred. In the author's clinic there have been ten cases of extirpation of the spleen with but four of notable improvement. This is somewhat better than the average, for an analysis of a large material shows only 20 per cent of notable improvement. The results of ileostomy or ileal artificial anus seem in no wise superior to those of splenectomy although the case material is still very small. The hypothyroid nature of this affection is borne out in practice by one isolated example of arrest under iodine treatment, the case reported by Holler in 1924. Meagre positive results have followed the vaccine treatment in which a *Bacillus coli* strain was employed. The use of arsphenamine seems to be justified from two different angles. First it may be regarded as an extension of the ancient treatment with inorganic arsenic and in the second place recent authorities in dark field illumination have claimed that the disease is due to a minute spirochete. Long before this discovery Byrom Bramwell had claimed that salvarsan was superior to all other arsenicals and in 1913 he reported a series of 21 cases treated with this

drug in which the results were of an encouraging character. Minkowski at once instituted this treatment at the Breslau clinic, and the case material now counts up to 59, in 39 of which no other treatment was employed. The percentage of positive cases in which the benefit was notable was over 45, while that of total failure was 25 and a fraction. The highest figure for inorganic arsenic conjoined with other methods was but 30 per cent with a failure of 48 per cent, the balance in both series being placed under the heading, "slight improvement."

Curative Pneumoperitoneum in Exudative Tuberculosis Peritonitis—T. Salvatore, in an article on this subject in *La Riforma Medica* of June 14, 1926, first refers to the great superiority of laparotomy, especially in the exudative form, in this affection of the peritoneum, despite the fact that the mechanism of recovery in these cases is still an impenetrable mystery. Lauenstein ascribes it to the action of light, Mosetig-Moorhof to that of air *per se*, and Floria to the oxygen content of the air. Several authorities who hold the latter view have injected oxygen directly into the peritoneal cavity. Silvestri after extensive original researches reached the conclusion that introduction of atmospheric air into the pleural and peritoneal cavities is the best treatment for tuberculous serositis, the air to be injected after withdrawal of the serous fluid and with its amount proportional to that of the latter. Grocco and others prefer oxygen alone and in the form of oxygenated water—a 5 to 10 per cent solution of the gas in distilled water or physiological saline for lavage. In recent years all of the preceding methods have been submitted to trial and numerous good results have been reported from the use both of air and of oxygen. The author describes in detail a case of tuberculous peritonitis in a man of 38 in which there was considerable ascites. After removal of 3200 cc of exudate the author injected 800 cc of oxygen into the peritoneal cavity. There was no actual thought of curing so serious a case with this simple resource, for the patient was evidently suffering from general tuberculosis, but tapping had been indicated for the relief of the symptoms. The temporary improvement was greater than could be explained by mere tapping and the chief use of pneumoperitoneum seems to have been in retarding the return of the ascites. It was not until two weeks after the operation that some fluid could be detected in the cavity (200 cc drawn off). Death took place in a little over 3 weeks from the first tapping.

been examined daily by the physician as he had in mind the child's various illnesses and the probable effect that the toxins therefrom might have had upon the heart, and at no time was there discoverable any heart condition. At the time of his morning visit on June 16th the defendant felt that the boy had sufficiently recovered not to need any further medical treatment and had advised the mother that he would not call again unless he was notified. At about 5 15 P M on June 16 he received word that the boy had died, and upon arrival at his home had found him dead. An examination disclosed no outward evidences of the cause of death. The mother told the defendant that at about 1 30 P M the child had eaten a hearty meal and that thereafter he had gone on the roof where he had been playing for

some time. That he came downstairs at about four o'clock in the afternoon, drank a half glass of milk and was then running around the room with his younger brother, jumping upon chairs, etc. That at about four o'clock he vomited, said that he did not feel well and would lie down. That the child had then gone to bed and died suddenly at 4 40 that afternoon.

As the defendant had been in attendance upon the child for several weeks the death certificate was made by him, the cause of death being given as acute endocarditis following mastoiditis, otitis media, contributory cause, measles.

The trial of the action lasted several days and upon submission of the case to the jury a verdict was returned in favor of the defendant and the complaint dismissed.

COLLECTION OF BILL—MALPRACTICE COUNTERCLAIM

An action was instituted by a physician to recover his bill for services rendered. As happens in a great number of these actions the patient filed a counterclaim charging the physician with negligence and carelessness in his treatment.

The patient had been under the physician's care during her prenatal period. There were no complications during this time. At about the time of delivery the patient went to the hospital. The first stage of labor was protracted and the patient became tired. Proper steps were taken by the physician to resuscitate the patient and give her rest. When examining the patient to determine the extent of dilatation the membranes ruptured. Thereafter the patient made fairly rapid progress. The second stage of labor was somewhat longer than normal, the uterus not being fully dilated and the use of forceps was considered by the defendant physician and the consultant who had been called in. However, the

patient made progress in her labor and was delivered with a slight tear of the perineum, which was immediately sutured. There were no complications after the delivery other than a slight inflammation of the nipples which cleared up within a day, and the patient left the hospital the sixteenth day after delivery. The relationship at that time between the physician and the patient was friendly. He rendered several bills for his services and these not being paid he pressed the patient for payment, but was met by a refusal upon the part of the patient to pay for the services rendered by the physician.

In order to collect his bill an action was instituted. After this action had been pending for some time the physician compromised with the patient, accepting a lesser amount than his bill in settlement of his claim, the counterclaim of alleged malpractice being withdrawn and the action being discontinued.

part of the individual practitioner is and should be held in contempt and disapproval, and yet if the work of the medical profession as a whole could be better known and understood without in anywise trespassing upon any of the sacred canons of professional conduct, it is believed that it would be an advantage not only to indi-

vidual doctors unjustly assailed and accused, but to the medical profession as a whole.

No definite plan for the accomplishment of this aim is advanced, except the suggestion that it is a matter worthy of the thoughtful study and consideration of the profession and of those who cherish its best interests

MASTOIDITIS COMPLICATED BY OTITIS MEDIA AND TONSILLITIS FOLLOWED BY DEATH FROM ENDOCARDITIS

An action was instituted against a physician by an administrator to recover for the death of his decedent claimed to have been caused by the negligent treatment rendered by the physician

The patient was seven years and four months of age at the time of his death. The complaint alleged that on April 29, 1922, the decedent was operated upon for mastoiditis and remained at the hospital where such operation was performed until May 5, 1922, when he was removed to a hospital for contagious diseases as the child had contracted measles. On May 18, 1922, the patient was discharged as having recovered from the measles and a certificate was issued by the Board of Health that he was free from that disease and could return to school. It was further claimed that the child at that time had not fully recovered from the mastoid condition and was in a weak and run-down condition, and on May 22, 1922, the defendant physician was engaged to attend and treat the patient, and that he did so from that date until June 16, 1922. It is claimed that the physician was negligent in his treatment in that he failed to discover the true condition of the patient, and on June 4 advised that the child was suffering from tonsillitis and that a tonsillectomy should be performed. That the child was not suffering from tonsillitis but was suffering from diphtheria, which the physician should have known as the throat was inflamed, membrane and white patches appeared upon it. That on June 7 the physician negligently and improperly performed a tonsillectomy upon the patient, and that between that date and June 16 his treatment was negligent, careless and improper in that he made no tests for diphtheria and that the medicines prescribed by him were for a sickness or disease from which the patient was not suffering. That on June 16 the patient died as a result of the physician's improper treatment. That the cause of death was improperly ascribed as due to measles and that the physician had negligently filed the death certificate with the Board of Health ascribing the cause of death as measles when in fact the death resulted from diphtheria.

The patient was first seen by the defendant physician at his home on May 22. Upon examination it was found that he was suffering from

a post-operative mastoiditis which was pussy. The wound was cleansed and dressed with an iodine solution, one part iodine to five hundred parts water. There was also prescribed a three-grain dose of calomel by mouth and a tonic of Fowlers solution with iron, quinine and strychnine. For the first three days the patient was seen twice a day and thereafter was seen daily. On each of the visits the wound was dressed in the manner similar to the first dressing. On May 27 an abscess which had formed in the ear canal was opened by the physician, releasing a great quantity of pus. At this time the patient was also suffering from tonsillitis which under proper treatment cleared up, and the child was also affected with an otitis media and a furunculosis. The furunculosis under the treatment of the defendant cleared up, but the otitis media did not clear. After the subsidence of the tonsillitis the otitis media not clearing the defendant advised the removal of the tonsils and adenoids so as to increase the drainage from the middle ear. On June 7 under a general anaesthesia of chloroform administered by another physician he performed an adeno-tonsillectomy. He remained with the child until he had fully come out of the anaesthesia. There were no untoward effects from this operation and no excessive bleeding. After the tonsillectomy the physician made daily calls, irrigating and dressing the ear upon each call. He also examined the throat, which presented the usual normal condition after the removal of tonsils. At no time was there any inflammation, swelling or white patches in the throat or the membrane thereof. The otitis media began to clear after the tonsillectomy on June 7.

On June 10, at the time the defendant called on the patient, the child was up on the roof of his home playing and was called down by his mother. The defendant continued to make daily visits until June 16. The ear condition had completely cleared. There was, however, a little pus in the throat for which condition there was prescribed a gargle of potassium chlorate, powdered alum and glycerine, one dram to six ounces of water. On the morning of June 16, at about ten o'clock, at the time of the defendant's call he carefully examined the child and found the heart and lungs in normal condition. The heart had

the Post, and that when immunizations were begun, the enlisted men objected, but readily consented after the children of the officers had been immunized

Dr Ormsby described the toxin-antitoxin work in the public schools of Amsterdam, and said that an effective object lesson was the death of a child to whom its parents had refused immunization. Dr Ormsby said that, while all the school children had been immunized at public expense, in the future the work would probably be left to the family doctors.

Dr H. A. Gilmartin of Schenectady, said that consents for giving toxin-antitoxin to school children had been obtained by school nurses who visited the parents and not only got their consents, but asked them to name the doctor whom they wished to give the immunizations. The Department of Health then informed the doctors of the names of those who would come for the immunizations and in this way the cooperation of the physicians was secured. The doctor said that a display card was given to each doctor stating that he was prepared to give the immunizations.

After the social supper at seven o'clock, given by the Hospital, the members and guests and the nursing staffs of the two hospitals of Plattsburg listened to addresses interspersed with musical number.

Dr D. S. Dougherty spoke on the topic "Sentiment in Nursing" and placed the nurse who is actuated by a love for humanity in contrast with the one who works principally for money. He spoke of the value of relaxation as a means of grace, and quoted Sir Thomas More:

'As onward we journey how pleasant
To pause and inhabit the while,
Some bright sunny spot like the present,
That midst the dull wilderness smile
But time like a pitiless master
Cries 'Onward' and spurs the gay hours

Oh, never does time travel faster
Than when its path leads through flowers
Oh then may our life's happy measure
Be all of such moments made up
They are born on the bosom of pleasure,
They die 'midst tears of the cup"

Dr George M. Fisher referred to the work of the State Society's special committee on nursing, which was seriously considering the proposition that every nurse should have two years of general bedside training, and then if the nurse wished to take up public health work, or other specialty, she should give another year to the extension study of that branch. He also advised the nurses to avoid giving medical advice—practicing medicine—and to stick to her nursing under the direction of the doctor.

Dr Horace M. Hicks described the early work of Florence Nightingale who, amid the opposition of generals and army surgeons, brought her own supplies to the Crimea by the shipload, and with gentlewomen as assistants, introduced methods of modern cleanliness where filth and vile smells and neglect had always prevailed.

A scientific session was held on the morning of October 2, at which the following papers were presented:

"Three Years Observations with Deep X-Ray Therapy and Radium" By Albert Lenz, M.D., Schenectady

"Infant Feeding and Its Problems" By Frank vander Bogert, M.D., Schenectady

"Colles Fractures" By Frederick F. McGauley, M.D., Schenectady

"Observations on Pernicious Anemia with Particular Reference to Recent Dietetic Treatment" By Thomas Ordway, M.D., Dean Albany Medical College

THE SEVENTH DISTRICT BRANCH

The twentieth annual meeting of the Seventh District Branch of the Medical Society of the State of New York, comprising the counties of Monroe, Wayne, Cayuga, Seneca, Yates, Ontario and Livingston, was held on Wednesday, September 29, 1926, in the County Club, Geneva, N. Y., with the President, Dr. Claude C. Lytle, of Geneva, in the chair and Dr. John A. Lichty, of Clifton Springs, Secretary. The day was perfect, and the clubhouse of the Country Club, overlooking Seneca Lake, made an ideal meeting place. The doctors attending the meeting were the guests of the Ontario County Medical Society at a buffet luncheon at noon.

President Lytle, in opening the morning session, said that those in charge of the program considered that one function of the District Branch meeting was to afford the opportunity for the County Society to report their activities, and that in carrying out that plan, the officers had arranged reports on toxin-antitoxin immunizations against diphtheria, and postgraduate work.

The experience of the City of Auburn in the suppression of diphtheria by toxin-antitoxin immunizations was described by Dr. George C. Sincerbeaux of Auburn. His description of the work, together with a general dis-

NEWS NOTES

FOURTH DISTRICT BRANCH

The twentieth annual meeting of the Fourth District Branch of the Medical Society of the State of New York, composed of the counties of St Lawrence, Franklin, Clinton, Essex, Hamilton, Fulton, Montgomery, Schenectady, Saratoga, Warren and Washington, was held on October 1st and 2nd in Plattsburg. Dr Horace M Hicks, of Amsterdam, presided as President. Three sessions were held, an afternoon meeting on public health on October 1st, an evening supper followed by popular talks, and a scientific session on the morning of October 2nd.

The new Physicians' Hospital, in which the sessions were held, is one of the most complete hospitals in existence, and embodies the experience gained by its promoters from a study of the most modern hospitals of America and Europe. It was the gift of Mr W H Miner who resides in the vicinity of Plattsburg and is deeply interested in local medicine. The hospital is designed for 250 patients, and is equipped with every modern convenience. It was opened for patients on January 1, 1926.

The members and guests of the Fourth District Branch were the guests of the hospital at a supper given to the doctors and their ladies.

Dr Hicks, in his Presidential address, referred to the great area of the Fourth District Branch devoted to recreation and health, for within the Adirondack State Park are located sanatoriums and health camps of world-wide fame. Dr Hicks also called attention to the public health features of the program, and congratulated the County Medical Societies on having done much public health work worthy of record.

Dr George M. Fisher, President of the Medical Society of the State of New York, emphasized the necessity of watchfulness over legislation during the coming winter, although the Medical Practice Act is in operation, great efforts will be made to undo it. Workmen's Compensation bills and welfare legislation will also be proposed. The members of each County Medical Society will find plenty of work to do in advising their legislators regarding medical bills.

Dr Daniel S. Dougherty, Secretary of the Medical Society of the State of New York, spoke of the ancient identity of the priest and the physician, and of the disinterested helpfulness which is still a characteristic of the doctor of medicine. The doctor quoted the lines inserted over the gateway of the Cardiac Hospital in London:

"I shall pass through this world but once

Anything that I can do, therefore, or any kindness I can show to any human being, let me do it now. Let me not defer or neglect it, for I shall not pass this way again."

Speaking of the success of the physician in meeting his altruistic obligations, Dr Dougherty quoted from Robert Louis Stevenson:

"Some men stand high above others. The soldier, the sailor, and the shepherd not infrequently, the artist rarely, rarer still the clergyman, the physician almost as a rule. He is the flower of our civilization. * * * He will be thought to have shared, as little as any, in the defects of the period and most notably to have exhibited the virtues of the race. Generosity he has, such as is possible to those who practice an art, never to those who drive a trade, discretion, tested by a hundred secrets, tact, tried in a thousand embarrassments, and what are more important, herculean cheerfulness and courage. So it is that he brings air and cheer into the sick room, and often enough, though not so often as he wishes, brings healing."

Dr E. Harrison Ormsby, President of the Medical Society of the County of Montgomery, described the public health activities and opportunities of the County Medical Societies of the Fourth District Branch. His paper is printed on page 859 of this JOURNAL.

Dr Earl H. King, of Saratoga Springs, discussed the principles of the periodic health examination. An abstract of his address is printed on page 861 of this JOURNAL.

Dr William L. Munson, of Granville, District State Health officer, suggested that an effective means of proving the sincerity of the advocates of periodic health examinations was that each promoter, lay or medical, should himself take an examination and thus set an example to others.

The anti-diphtheria campaign was presented from the practicing physician's point of view, by Dr William H. Ladue, of Plattsburg, and from the health officer's viewpoint by Dr Leo F. Schiff, health officer of the city of Plattsburg, and there was not much difference between the two. A considerable part of the discussion was over difficulties in the way of giving toxin-antitoxin immunizations. It does not seem to take much of a mole-hill to appear to be a mountain of objection to some persons. One prominent educator, for example, who objected to toxin-antitoxin has a sister who is a chiropractor.

Col. Huntington, Medical Officer at Plattsburg Barracks, said that there were 200 children at

suggested that the code might be modified so as to permit older physicians who find it difficult to continue their general practice, to engage in fraternal practice if they desired to do so. He also suggested that the County Society should take a greater interest in the conduct of the local hospital.

"What progress have we made in the past five years?" Dr W J Kennedy, speaking on this subject, said that the best indication of the progress made in the last five years was in the improved character of the papers that are being read before the Society.

"Were the local post-graduate courses such as we held last winter, a success, and should we have another course this year?" Dr George Lenz stated that the post-graduate course had achieved a marked success and those who had been able to attend it were eager that another course should be instituted this year. An epidemic of influenza which occurred at the time the course was given, reduced the attendance and some others were unable to attend because the meetings were held in the afternoon. He recommended, therefore, that if a course were undertaken this year it should be given in autumn and in the evening.

"Should we take more active interest in the function of our Board of Health?" Dr H C Denham, President of the Board of Health, urged the members of the Society to take a more active interest in the function of the Board of Health and in its personnel. He

suggested that the Society should recommend to the Mayor candidates for appointment to the Board when vacancies occurred.

"What is our attitude toward the various welfare organizations of the community?" Dr H B Riggs said that he thought the Society bore an attitude of restraint toward the activities of voluntary agencies, and realized that some might consider it debatable as to whether the Society should interest itself more actively, but gave it as his opinion that the County Society should consider the programs of all agencies whose activities led them into the field of health, and grant their approval wherever possible.

"What are our greatest faults as a Medical Society and in what ways should we progress in the future?" Dr A C Hagedorn agreed with Dr McKillip in feeling that the Society might consider a modification of its code of ethics, but, on the whole, he felt that the Society is doing splendid work.

Dr H H Oaksford made a few humorous remarks in response to "What is the proper way to conduct an outing of the Medical Society?"

Dr Fisher and Dr Lawrence were called upon to open discussions on the subjects, and Dr Sloan was asked to enlighten the Society on the work of his committee.

Comments at the close of the meeting indicated the wisdom of occasionally having a program of this character.

DELAWARE COUNTY MEDICAL SOCIETY

The following account of recent activities of the Delaware County Medical Society was received from Dr Robert Brittain, of Downs ville, N Y.

Through the kind auspices of Wilfred W Fry of Philadelphia, a former Delaware County boy, the Delaware County physicians were invited to attend a supper at Meredith Inn in honor of Ross V Patterson, M D, Dean of Jefferson Medical College, Philadelphia, Pa. Another distinguished guest was Dr Mendel, another Delaware County boy. These men all gave after-dinner talks which were very much enjoyed, as also was the supper. Nearly every member of the profession in the county was present, and not one invalid was found among them as was seen from the manner the supper was devoured. Such an innovation in the lives of a county physician breeds good fellowship, and more interest in our work. This supper and talks will go down in memory as a noted event.

The Delaware County Medical Society held a meeting on the evening of September 7, in the interests of popular Medical Education. Fifteen

of the twenty-two members of the society met in Downs ville for a social supper at six o'clock, after which the doctors went to the Opera House and representatives of their number addressed an audience of one hundred persons on health. Topics in which the people of the town were interested. Dr R. D Champlin and Dr Frank W Laidlaw, Health Officers, described the duties of people during an epidemic. Dr Harris A Houghton, of New York City, talked on the presentation of general diseases. Dr Meeker, of the State Education Department, talked on the preservation of the teeth. Addresses were also made by physicians from Delaware County, Dr T L Craig of Davenport, Drs W G Smith and W B Morrow of Walton, and Dr J E Safford of Stamford.

The meeting was unique in that it was designed for the direct benefit of the citizens of Delaware County. The people were interested not only in the subjects that were presented but doubly so because the topics were presented by their own local physicians.

cussion of toxin-antitoxin, is printed on page 857 of this JOURNAL

Dr Allen, health officer of the Village of Clyde, Wayne County, said that the work of giving the Schick test and immunizations was begun in Clyde three years ago. Practically all the school children had been immunized, with the result that the only case of diphtheria that developed among school children was in a child in whose family there were other cases of diphtheria. All the physicians of Clyde had taken turns in giving the immunizations to the pupils.

Dr B J Slater, of Rochester, presented the subject, "Postgraduate Work in the District, Is It Worth While?" An abstract of his address is printed on page 854 of this JOURNAL.

Dr George M Fisher, President of the Medical Society of the State of New York, gave an address in which he outlined the ever increasing number of benefits which the State Society brings to the practicing physician, and showed how the doctors could obtain those benefits through their County Medical Societies. He especially emphasized the post-

graduate work offered to the county societies, and told the members that they could obtain instruction in any subject they might choose.

The scientific part of the program consisted of three topics, all concerning early signs of disease. The first paper was "The Early Diagnosis of Diabetes," by Dr Floyd R Wright, of Clifton Springs.

"The Importance of the Early Recognition of Urologic Pathology," was the subject of a paper by Dr Henry G Bugbee, of New York City.

Dr Clayton W Greene, of Buffalo, discussed "Essential Hypertension," by which he meant increased blood pressure without evident symptoms and signs of involvement of the kidneys or heart. However, Dr Greene suggested that refined methods of study might reveal a beginning involvement of these organs.

The meeting was well attended and the members showed a deep interest in the scientific papers and in the reports of work done by the County Medical Societies.

THE HERKIMER COUNTY MEDICAL SOCIETY

On Tuesday, September 14th, Dr George M Fisher, President of the State Society, and Dr Joseph S Lawrence, Executive Officer, visited the Herkimer County Medical Society. The meeting was held at Pine Crest Sanatorium, where the members were guests of Dr Parkinson, Superintendent of that institution.

Dr John L Crofts, of Newport, read a very interesting and instructive paper on "Headaches and Their Causes." In the absence of Dr H A Bray, of Ray Brook, who was to read a paper on "The Diagnosis of Tuberculosis," Dr H J Ball, the district State health officer, was called upon to inform the Society concerning the State Department of Health's

tuberculosis program for the county. Dr Ball also spoke of the anti-diphtheria campaign.

Dr Fisher and Dr Lawrence continued the discussion of the anti-diphtheria campaign and urged the members of the County Society to aid the campaign by immunizing all the children in their families, and particularly those between the ages of six months and six years.

The Society adopted a resolution to this effect and also decided to make public their resolution.

Several members urged that the County Society take steps toward securing a county laboratory. A committee was appointed to take up the matter and report at a future meeting.

THE FULTON COUNTY MEDICAL SOCIETY

Thirty-five members of the Fulton County Medical Society accepted the invitation of their secretary, Dr A M Brown, to dine at the Sir William Johnson Country Club, Gloversville, on Friday evening, September 17th. There were also present as invited guests, Dr George M Fisher, President of the State Society, Dr Joseph S Lawrence, Executive Officer, and Dr Andrew Sloan, chairman of the sub-committee to study the nursing problem.

Invitations to the meeting announced that the evening would be devoted entirely to a

consideration of the conduct and workings of our County Society, and accordingly, after a short business session, Dr Ehle, President of the Society, announced the following program.

"What constitutes a healthy County Medical Society? Is our Medical Society in a healthy condition?" Dr B G McKillip, responding, said that, in his opinion, the County Society is in a healthy condition, but that it could improve its standing by a consideration of the code of ethics under which it is operating. He

THE DAILY PRESS

LIFE'S MYSTERIES

The New York *Herald-Tribune* of October 4 contains a description of a sermon preached by Dr Harry Emerson Fosdick to the congregation of the New Park Avenue Baptist Church, which is well known because its building is the gift of John D Rockefeller Dr Fosdick said

"There are four great questions about life Whence did we come, why did we come, how did we come, whither do we go? Science, which so many people suppose is going to crowd out religion, touches only one of them

"How did we come? That is science's field Science discovers for us the methods and processes of nature and life Marvelous have been its contributions It tells us how things have come But whence? And why? And whither?

"A book," he began, 'on the relationship between science and religion recently ended with this ultimatum 'Mysteries must give way to facts' In that curt and summary dictum is concentrated a large amount of popular thinking

'With strange cocksureness in university lecture halls, popular magazines and Sunday supplements, we find ourselves on tiptoe expectantly awaiting the solution of the last mystery A thoughtful man may well grow suspicious of

this superficial talk about the end of mystery The fact is the more one knows about the world, the more mysterious it is

But in religion itself, as a vital, saving and sustaining power in human experience, we are so deeply interested that here in New York, which some ministers are leaving because it seems hopeless and other ministers are refusing to come to because it seems obdurate and hard, we are proposing to erect a fresh and high standard of non-sectarian Christianity We are sure that in New York or out of it man cannot live without religion"

The subject of the conflict of science and religion has been prominently before the public for some years, and if the truth were told, most physicians are indifferent to the discussion Dr Fosdick states the viewpoint of most physicians when he enumerates the four great questions of life, and says that science, (including medical science) answers only the questions that concern the past A physician is the last person who would wish to destroy true faith, for it leads to a serene outlook and expectation which leads to rest and health

THE APE-MAN OF JAVA

Further light on the first of the fundamental questions of life stated by Dr Fosdick is the discovery of a complete skull of the Ape-Man of Java, as announced in the daily papers of September 28 The *New York Sun* of that date says

"Prof Heberlein of the Netherlands Government medical service has discovered at Trinil, in Central Java, a complete skull of the prehistoric apelike creature termed by some the "missing link," and by science, *Pithecanthropus erectus*

'The skull was found at the same place where Prof Eugene Dubois of Amsterdam University discovered in 1892 the upper part of a skull, two teeth and a thigh bone, from which was reconstructed the previously unknown apelike human designated as *Pithecanthropus erectus*

"Prof Heberlein's specimen, which is complete and sound, will be kept in Dutch East India, as the exportation of such relics is prohibited"

The word *Pithecanthropus* means simply ape-man, and is derived from two Greek words "pithecos," ape, and "anthropos," man The translation of the full scientific name is The Great Ape-Man

Science is answering the question, "Whence came we?" as it is slowly reading the record of man's dim past written in rocks buried safe in Mother Earth It is a story of continuous upward progress If history reveals the future, the story of man's ascent, physically and mentally and spiritually is an assured basis for expecting nobler planes of human life that are portrayed by prophets and godly seers

The story of man, the animal, is paralleled by that of the elephant One line of ancestral elephants developed great upper jaws which enabled them to browse on trees which were the dominant type of vegetation in later periods of geological time But at the same time another branch developed their lower jaws to uncouth lengths, with which they dug roots for food until they all starved to death because they could not chew and digest tough tree-roots

Man, too, has developed along diverse lines One line has lived in trees, as their descendants still do in the African forests, and as a result they are still wild men of the woods Another branch lived in huts raised above marshes and lakes, and their descendants have remained "clam diggers"

COLUMBIA COUNTY MEDICAL SOCIETY

The Columbia County Medical Society held its 120th semi-annual meeting on the morning of Tuesday, May 11, 1926, in the Taconic Inn, Copake. Three-fifths of the membership attended the meeting, which was one of the most successful ever held. A pleasing feature was a social dinner at noon.

The application of Dr. Helen M. Deane, of the State Training School for membership, was received and acted upon favorably.

The membership of Dr. L. J. Early, of this city, was transferred from the Albany County Society to that of Columbia County.

Dr. S. V. Whitbeck, of this city, chairman of the Committee on Public Health and Post Graduate Education, reported that a very successful course in "Pediatrics and Infant Welfare," was being given every Thursday night at the City Hospital, Hudson.

The society went on record as being in favor of

toxin-antitoxin for children as a diphtheria preventative.

The committee which was to report on a county public laboratory asked for and was given further time in which to make a report.

Dr. G. M. Fisher, of the State society, spoke of the progress being made by the society in advancing the ideals of the profession.

Dr. H. L. K. Shaw, of Albany, gave an enlightening talk on the infections of the urinary tract of children.

Dr. J. P. Ruppe, of the Philmont Sanatorium, received the approval of the society in regard to his efforts for the erection of an addition to the sanatorium to accommodate juveniles.

The Committee on Public Health was instructed to send a protest on the part of the county society to the Congressman protesting against amendments of the Harrison drug act.

THE NEW YORK ACADEMY OF MEDICINE GUIDES TO GRADUATE STUDY

The New York Academy of Medicine has issued a series of guides to postgraduate instruction in Greater New York. A booklet giving detailed information regarding the hospitals of Greater New York was reviewed on page 682 of the August first issue of this Journal. This booklet gives data regarding the clinics and other forms of instruction that are available in each hospital.

The Academy has supplemented the booklet with a series of twelve others written from the standpoint of subjects of instruction, and containing synopses of approved courses given in those topics in the several hospitals. The subjects of the series of pamphlets are

- 1 Dermatology and Syphilology
- 2 Obstetrics and Gynecology
- 3 Internal Medicine
- 4 Ophthalmology
- 5 Oto-laryngology
- 6 Pediatrics
- 7 Surgery
- 8 Urology
- 9 Neurology and Psychiatry
- 10 Orthopedic and Rehabilitation Surgery
- 11 Roentgenology

12 Public Health, Health Examinations, and Fundamental Medical Science subjects

These guides form a part of the service offered by the New York Academy of Medicine to physicians everywhere. The announcement printed in each synopsis says

"The Committee on Medical Education of the New York Academy of Medicine has for some time been studying the opportunities for graduate medical education offered in New York City. Its approval has been lent to those courses only which were found to be well organized, with adequate equipment and clinical material, and given by physicians of character who are known to be qualified teachers in their special lines of work.

"The investigation has been carried on by a number of sub-committees, which have surveyed the courses offered and have reported their recommendations to the full committee."

Any of these synopses will be sent free to any doctor who applies to the Bureau of Clinical Information, New York Academy of Medicine, 17 West 43rd Street, New York, N. Y.

BOOKS RECEIVED

Acknowledgment of all books received will be made in this column and this will be deemed by us a full equivalent to those sending them. A selection from this column will be made for review, as dictated by their merits, or in the interests of our readers.

A HISTORY OF THE MASSACHUSETTS MEDICAL SOCIETY WITH BRIEF BIOGRAPHIES OF THE FOUNDERS AND CHIEF OFFICERS By WALTER L. BURRAGE, A.M., M.D., Secretary of the Society Illustrated with views of meeting places, reproductions of old documents and portraits of important officers Privately printed, 1923

THE ESSENTIALS OF PHYSIOLOGY INCLUDING THE PHARMACODYNAMICS OF THE IMPORTANT TYPICAL DRUGS By GEORGE BACHMANN, M.S., M.D., and A. RICHARD BLISS, Jr., A.M., Ph.D., M.D. 343 pages, 178 illustrations Phila., P. Blakiston's Son and Co., 1924

A COMPEND OF OBSTETRICS Especially Adapted to the Use of Medical Students and Physicians Revised and Edited by Clifford B. Lull, M.D. Tenth Edition. 16mo of 283 pages with 84 illustrations Philadelphia, P. Blakiston's Son and Co., 1925 Cloth, \$2.00 (Blakiston's Compend)

LOCAL ANESTHESIA IN OTOLARYNGOLOGY AND RHINOLOGY By JAMES JOSEPH KING, A.B. M.D. Octavo of 205 pages, with 21 illustrations New York, Paul B. Hoeber, Inc., 1926 Cloth, \$5.00

SURGERY OF CHILDHOOD By JOHN FRASER, M.C. M.D. Two octavo volumes of 1152 pages with illustrations. New York, William Wood and Company, 1926 Cloth, \$14.00

ELECTROTHERMIC METHODS IN THE TREATMENT OF NEOPLASTIC DISEASES Designed as a Practical Handbook of Surgical Electrotherapy for the Use of Practitioners and Students By J. DOUGLAS MORGAN, B.A., M.D. 12mo of 172 pages, with illustrations Philadelphia, F. A. Davis Company, 1926 Cloth, \$2.50

THE HUMAN CEREBROSPINAL FLUID An Investigation of the Most Recent Advances as Reported by The Association for Research in Nervous and Mental Disease. Editorial Board, CHARLES L. DANA, M.D., and others Octavo of 568 pages, with 77 illustrations. New York, Paul B. Hoeber, Inc., 1926 Cloth, \$10.00 (Association for Research in Nervous and Mental Disease. Volume IV [1924])

SURGERY OF NEOPLASTIC DISEASES BY ELECTROTHERMIC METHODS By GEORGE A. WYETH, M.D. Octavo of 298 pages, with 137 illustrations New York, Paul B. Hoeber, Inc., 1926 Cloth, \$7.50

THE MODERN TREATMENT OF HEMORRHOIDS By JOSEPH FRANKLIN MONTAGUE, M.D., F.A.C.S. Octavo of 296 pages, with 116 illustrations Philadelphia and London, J. B. Lippincott Company, 1926 Cloth, \$5.00

AN ATLAS OF MIDWIFERY By COMYNS BERKELEY, M.A., M.C., M.D., and GEORGES M. DUPUY, M.D. Octavo of 160 pages with illustrations. New York, William Wood and Company, 1926 Cloth, \$3.00.

PRACTICAL ULTRA-VIOLET LIGHT THERAPY A Handbook for the Use of Medical Practitioners. By T. Clyde McKenzie, M.B., Ch.B., and A. A. King Octavo of 108 pages, with illustrations New York, William Wood and Company, 1926 Cloth, \$2.50

HANDBOOK OF MEDICAL ELECTRICITY AND RADIOLOGY By JAMES R. RIDDELL, F.R.F.P.S. 12mo of 239 pages, with illustrations New York, William Wood and Company, 1926 Cloth, \$2.75

ORTHOPÆDIC SURGERY By W. A. COCHRANE, M.B., Ch.B. Octavo of 528 pages, with illustrations New York, William Wood and Company, 1926 Cloth, \$6.50

CANNULA IMPLANTS AND REVIEW OF IMPLANTATION TECHNIQUES IN ESTHETIC SURGERY By CHARLES CONRAD MILLER, M.D. 12mo of 99 pages, with illustrations Chicago, The Oak Press, 1926 Cloth, \$2.00

THE DUODENAL TUBE AND ITS POSSIBILITIES By MAX EINHORN, M.D. Second edition, revised and enlarged. Octavo of 206 pages, with illustrations. Philadelphia, F. A. Davis Company, 1926 Cloth, \$3.00.

PRACTICAL MATERIA MEDICA AND PRESCRIPTION WRITING By OSCAR W. BETHEA, M.D., Ph.G. Fourth revised edition. Octavo of 498 pages with illustrations Philadelphia, F. A. Davis Company, 1926 Cloth, \$4.50

RADIOTHERAPY IN RELATION TO GENERAL MEDICINE By FRANCIS HERNIMAN-JOHNSON, M.D. 16mo of 211 pages London and New York, Oxford University Press, 1926. Cloth, \$1.75 (Oxford Medical Publications)

DISEASES OF CHILDREN A Short Introduction to Their Study By HECTOR CHARLES CAMERON, M.A. M.D. 16mo of 199 pages. London and New York, Oxford University Press 1926 Cloth, \$1.75 (Oxford Medical Publications)

THE SURGERY OF GASTRO-DUODENAL ULCERATION By CHARLES A. PANNETT, B.Sc., M.D. Octavo of 154 pages, with illustrations London and New York, Oxford University Press, 1926 Cloth, \$3.25 (Oxford Medical Publications.)

BRAIN AND HEART Lectures on Physiology By GIULIO FANO. Translated by HELEN INGLEBY Octavo of 142 pages, illustrated London and New York, Oxford University Press, 1926 Cloth, \$2.75 (Oxford Medical Publications)

STUDIES IN INTRACRANIAL PHYSIOLOGY AND SURGERY The Third Circulation, The Hypophysis, The Gliomas By HARVEY CUSHING, M.D. Octavo of 146 pages illustrated. London and New York, Oxford University Press, 1926 Paper, \$3.25 (Oxford Medical Publications)

even until now Other branches lived on the open plains where dangers constantly threatened, but where there was boundless opportunity and even the necessity to conquer Nature, and to progress along all the lines that go to make the modern man of highly civilized nations

Viewing the long line of human progress from the *Pithecanthropus erectus*, up through the low browed Neanderthal man to the present *Homo sapiens*, what scientist will dare to deny the

probability of his future development into the *Homo angelicus*?

The American Museum of Natural History, at 77th Street and Eighth Avenue, New York City, contains exhibits of casts and restorations of the skulls of primitive men, including that of the first Java ape-man to be discovered by Dubois The May-June, 1920, issue of the magazine, *Natural History*, published by the Museum, contains photographs of some of the more striking exhibits illustrating the ascent of man

CANCER CONTROL

The newspapers have carried column notices of the International Cancer Symposium held in Lake Mohonk during the last week in September The *New York Times* of September 25 says

"For the first time in the history of medicine, experts from Europe, Canada and the United States agreed here today on an authoritative statement of the present state of scientific knowledge concerning cancer

"The statement, which is designed to aid the medical profession and public generally, was made public by Dr George A Soper, managing director of the American Society for the Control of Cancer, at the close of a five-day international cancer symposium held here under the Society's auspices

"More than one hundred specialists, leaders in their respective countries, joined in issuing the statement"

The statement is designed for educating the people It is carefully written in order to carry scientific weight, and its items are carefully modified in order to secure accuracy For example, the statement says

"Although the causation of cancer is not completely understood, it may be accepted that for all practical purposes cancer is not to be looked upon as contagious or infectious"

Other items of information contained in the statement are

"Cancer in some parts of the body can be discovered in a very early stage, and if these cases are treated properly the prospect for a permanent cure is good

"The cure of cancer depends upon discovering the growth before it has done irreparable injury to a vital part of the body and before it has spread to other parts

"The public must be taught the earliest danger signals of cancer which can be recognized by persons without a special knowledge of the subject, and induced to seek competent medical attention when any of these indications are believed to be present

"The most reliable forms of treatment and, in fact, the only ones thus far justified by experience and observation, depend upon surgery, radium and X-rays

"Efforts toward the control of cancer should be made in two principal directions, the promotion of research in order to increase the existing knowledge of the subject and the practical employment of the information which is at hand"

While these statements are not new, yet they are authoritative, and are the opinions of the leading cancer experts in the world

PRISON DIET

A Nebraska County Judge has been achieving notoriety recently by giving prohibition offenders prison sentences with a bread and water diet The judge is reported as trying a bread and water diet on himself for five days with the result of "a loss of ten pounds weight and a renewed determination to punish every liquor law violator with a similar sentence in jail"

The reports say that the sheriff also underwent a self-imposed diet of bread and milk,

in order to judge what a bread and water diet would be like He too had lost ten pounds, but still weighs 264 pounds

Such experiences and experiments as these mean nothing Almost any adult would stand a good chance of being benefited by a strict bread and water diet for several days The principal bad effects of the diet would result from a deficiency of certain food elements, but they would not be likely to appear under several weeks

A MANUAL OF HYGIENE AND SANITATION By **SENECA EGBERT, A.M., M.D., Dr.P.H.** Eighth edition, enlarged and thoroughly revised. Octavo of 616 pages, with illustrations. Philadelphia and New York, Lea and Febiger, 1926. Cloth, \$4.00

Dr Egbert in this work demonstrates very comprehensively his thorough knowledge of this all important science. In this edition he has made such revision as to keep his manual apace with the modern advances made in the field which this volume covers.

The introductory chapter is very impressive and enthruses one to read on to get new ideas regarding hygiene and sanitation.

The work is very systematic. It reveals the modern attitude, trend and accomplishments in this broad field which is drawing universal attention.

The book is well written and covers the subject in a clear, concise way. We would not hesitate to recommend its use by all students of hygiene and sanitation.
J J W

NEURITIS AND NEURALGIA. By **WILFRED HARRIS, M.D., Cantab, F.R.C.P., Lond.** Octavo of 418 pages, with illustrations. New York, Oxford University Press, 1926. Cloth, \$4.00 (Oxford Medical Publications)

There are but a few terms that are as loosely used by the medical profession as neuritis and neuralgia. In fact, the knowledge of the average medical practitioner regarding these terms is quite hazy. The author has treated the subject in a lucid, literary style, and has presented it to the profession in a manner that ought to arouse interest in the subject. The book is profusely illustrated. There are references to many articles dealing with different phases of the subject. The author has drawn mainly from his own practice which apparently is a mighty large one and covers several decades. There is a great need for just such a publication, as both the neuritic as well as the neuralgic conditions have been greatly neglected.

IRVING J SANDS

BLOOD CHEMISTRY COLORIMETRIC METHODS FOR THE GENERAL PRACTITIONER. With Clinical Comments and Dietary Suggestions. By **WILLARD J STONE, B.Sc., M.D.** Second Edition, revised. Octavo of 129 pages. New York, Paul B Hoeber, Inc., 1926. Cloth, \$3.25

The second edition of this book continues as an excellent compend of chemical analysis of the blood. It is characterized by succinctness and clarity. The methods of procedure are chosen for their simplicity and accuracy. An excellent summary of the significance of the various blood findings is given. It is of special value to the technician, internist and genito-urinary surgeon. In any laboratory it will prove to be a useful supplement to more elaborate works on chemical analysis of the blood.
M WISNEFSKY

MATERIA MEDICA AND THERAPEUTICS, INCLUDING PHARMACY AND PHARMACOLOGY By **REYNOLD WEBB WILCOX, M.A., M.D.** Eleventh Edition. Octavo of 798 pages. Philadelphia, P Blakiston's Son and Company, 1926. Cloth, \$5.00

This old standard, coming back for the 11th time, has been revised to conform to the new pharmacopoeia. Some change in arrangement, placing the drugs under their leading physiologic action, is an improvement and in accord with the tendency of the times. In other particulars this volume follows the arrangement of its well known predecessors. Time is clarifying the muddled therapy of yesterday. It would be interesting to compare many of the statements in this edition regarding pharmacologic action with statements made in the 1st edition about the same drugs.
M. F DEL.

TEXT-BOOK OF MATERIA MEDICA FOR NURSES Compiled by **LAVINIA L. DOCK, R.N., and JENNIE C. QUIMBY, R.N.** Eighth Edition. 12mo of 317 pages. New York and London, G P Putnam's Sons, 1926. Cloth, \$2.25

This issue is the eighth edition. Evidently the book is supplying a need and well it may, as it is one of the best of its kind. Its 300 pages provide a liberal store of information of value to nurses and it can be recommended for this purpose.
M F DEL.

THE PRINCIPLES AND PRACTICE OF ENDOCRINE MEDICINE. By **WILLIAM NATHANIEL BERKELEY, Ph.D., M.D.** Octavo of 368 pages, with 56 illustrations and 4 colored plates. Philadelphia and London, Lea and Febiger, 1926. Cloth, \$4.50

The field of endocrinology while at present very speculative bids fair in the near future to add more and more to definite practical curative medicine.

The author of this small volume has made a sincere and successful effort to present this difficult subject in a simple and practical way and has presented many details of treatment and dosage.

The volume is made up of fifteen chapters describing the morphology of the glands of internal secretion, alterations in structure, physiology and results of altered secretion, lack of secretion or excessive activity. Separate chapters are devoted to the subject of basal metabolism and the influence of endocrine on growth, old age and obesity.
H M F

SIXTY YEARS IN MEDICAL HARNESS Or the Story of a Long Medical Life, 1865-1925. By **CHARLES BENJULYN JOHNSON, M.D.** Octavo of 333 pages. New York, The Medical Life Press, 1926. Cloth, \$3.00

This book is an interesting mass of details in the reminiscences of a country doctor, who practised during the most eventful and most progressive period of medical history. Starting with the Civil War in which, as a steward, Dr Johnson tells of the surgical difficulties of those war days. He then depicts the trials and tribulations of his medical student years. His teachers in the various medical schools are vividly portrayed. Dr Johnson gives us an accurate account of the medical colleges of the 60's and 70's with their limitations as to adequate teaching staffs and adequate teaching facilities.

The account of his struggles as a recent graduate trying to establish a practice in a rural community is enlivened and embellished by numerous interesting and amusing anecdotes. He reveals the hardships encountered in practising in a sparsely populated district with the lack of conveniences even in those inconvenient days.

But what is most absorbing in Dr Johnson's book is his accurate and detailed descriptions of the medical men of note with whom he came in contact or was at some time or other associated during his sixty years of active practice, for he thus transmits good word pictures of these men for use in medical annals.

This book is very well written. Its moderate price places it within the reach of everybody. The book should meet the hearty welcome it deserves.

WM RACHLIN

OPHTHALMIC NEURO-MYOLOGY A Study of the Normal and Abnormal Actions of the Ocular Muscles from the Brain Side of the Question. By **GILES C. SAVAGE.** Second Edition. Octavo of 227 pages, illustrated. Nashville, Tenn., McQuiddy Printing Co., 1926. Cloth, \$3.00

After a lapse of over twenty years, the second edition of Dr Savage's book has appeared.

The preface to this edition states "Pages six to twelve have been rewritten because of the discovery that the eye has only two axis of rotation."

A new table showing the action of the eye muscles concerned in the various rotations has been constructed and is set forth on page eleven.

BOOK REVIEWS

THE CRIPPLED HAND AND ARM By CARL BECK, MD
Philadelphia and New York, J B Lippincott Company, 1925 Octavo of 243 pages, with 302 illustrations

Contributions in monographic form seems to be the vogue. Representing, as a rule, the most important effort of an author's life work, they are splendid auxiliaries to one's text book, volumes on general medicine or surgery and a valuable adjunct to the reference shelf.

Carl Beck's volume, "The Crippled Hand and Arm," deserves such a place, not perhaps because of its profound treatment of all the problems of hand, forearm and arm surgery, but because of the enthusiasm and optimism which is evinced by him for his subject and which he has attempted to pass on to his readers.

The chapter dealing with the congenitally deformed hand seemed most interesting. Beck illustrates the advantage of carefully planned stage operations for the correction in part at least of such distressing deformities as ectrodactyly (clump or drumstick hand).

The first three chapters are introductory. Function, anatomy and physiology are discussed. These are followed by individual chapters on injury, mutilation, burns and disease in their relation to the crippled hand.

The concluding 100 pages or part II of the volume deals with the wrist, elbow and shoulder lesions in relation to the hand. Illustrations are numerous, the line drawings very good and the photographs instructive.

DONALD E. McKENNA

SEX AND EXERCISE—A STUDY OF THE SEX FUNCTIONS IN WOMEN AND ITS RELATION TO EXERCISE. By ETTIE A. ROUT (Mrs F. A. Hornibrook). Foreword by A. C. HADDON, M.A., ScD, F.R.S. William Wood and Company, New York, 1925. Price, \$2.25.

For the female of the species, at any rate, there exists (in the author's opinion) a close relationship between the sex function and the physiological efficiency of the muscles of the abdominal, gluteal and pelvic parts of the trunk. When these muscle groups are at or above par, constipation vanishes and sexual frigidity, whose frequent cause is intestinal stasis, disappears. To support her contentions, the author points to the remarkable physical and marital efficiency of the semi-savage races and tribes whose muscular and sexual perfection are due, it is claimed, to their native dances. For us "civilized" folk, the author urges the adoption of a "system of exercise based on the native dances" so as (1) To stir into healthful activity the whole of the abdominal and pelvic organs (2) To prevent or remove the most objectionable feature of civilized humanity—the protuberant belly and the overhanging buttocks (3) To strengthen and improve the muscles of the pelvic diaphragm which support and operate the organs of generation and evacuation.

Just how to accomplish these desiderata is set forth in part three of the volume, actual photographs being employed to accompany the descriptions of the exercises that are recommended. As an illustrated physical culture manual, the book is of some value, but it is difficult to subscribe to the author's radical views on eugenics and birth control.

FRANK E. MALLON

THE OLD TIME COUNTRY DOCTOR. A special article published in *The Journal of the American Medical Association*. By WILLIAM ALLEN PUSEY. American Medical Association Press, 1925.

This is a very brief but remarkable portrayal of the common sense practice of an old time country doctor as depicted by his own son.

WM. RACHLIN

INTERNATIONAL CLINICS. Edited by HENRY W. CATTELL, A.M., M.D. 35th series, Volume II. Octavo of 311 pages, illustrated. Philadelphia and London, J B Lippincott and Company, 1925.

The International Clinics have always stood out in their type and this volume is no exception. The first article is given over to some very interesting portraits of medical men, past and present, and should prove delightful reading to the younger men who are interested in medical history.

There is a splendid paper on kidney affections. It was interesting to see that the author favored the Volhard and Fahr classification.

A paper entitled "The patient or his disease" is pregnant with facts the younger man is likely to overlook in his eagerness to come to a conclusion. It could stand repetition many times.

The newborn comes in for a paper on intracranial pressure which tells us much.

The surgical papers include Reconstruction Surgery by Albee, abscesses about the rectum and anus, and chronic purulent otitis complicated with chronic mastoid.

Abdominal diagnosis, Medical Reserve of the United States Army, unusual clinical cases and chronic infectious arthritis round out an exceedingly interesting volume.

KENNETH MACINNIS

EVOLUTION, GENETICS AND EUGENICS. By HORATIO HACKETT NEWMAN. Second Edition. Octavo of 639 pages, with illustrations. Chicago, University of Chicago Press, 1925.

This book presents a very complete survey in an historical as well as in a technical way of the subjects given in the title. It represents a great deal of effort, and forms a very handy and valuable reference work for anyone interested in these subjects, and a very good guide for physicians. Heredity in medicine is sort of an etiologic grabbag for the diseases the etiology of which is unknown. A careful reading of this book will help physicians to understand that heredity is not responsible for many of the conditions from which man suffers. We recommend this book heartily.

J. ARTHUR BUCHANAN

AN INTRODUCTION TO SURGERY. By RUTHERFORD MORISON, M.D., and CHARLES F. M. SAINT, M.D. Second Edition. Octavo of 347 pages, with illustrations. New York, William Wood and Company, 1925. Cloth, \$4.50.

This small volume of over three hundred pages is arranged in a very compact and lucid form, containing many illustrations of an instructive nature.

Not only is it a handy volume for the general medical man and surgeon but also a ready compend for the students of medicine, for whose aid this volume has chiefly been published.

The surgical conditions described are quite complete without the addition of masses of surgical details generally found in text-books on surgery.

RALPH F. HARLOE

NEW YORK STATE JOURNAL of MEDICINE

PUBLISHED BY THE MEDICAL SOCIETY OF THE STATE OF NEW YORK

Vol 26, No 21

NEW YORK, N Y

November 1, 1926

THE PAST, PRESENT AND FUTURE OF PREVENTIVE MEDICINE*

By MATTHIAS NICOLL, JR, M D, STATE COMMISSIONER OF HEALTH, ALBANY, N Y

WHEN, by the wondrous and much maligned process of evolution and after countless ages, man's more immediate ancestors emerged from the slime and ooze of a naked world, they shared with the prehistoric beasts of field and forest highly developed physical properties for defense and attack—mighty muscles, protective body covering, acute hearing, eyesight and sense of smell which enabled them to resist the ever present menace to their survival. But physical powers alone could have been of little avail, and the stock from which we sprung must inevitably have succumbed to the onslaughts of other species in whom such properties were equally or more highly developed. But fortunately for them and us, their descendants, in the human race alone physical development was accompanied by a comparatively rapid growth of the brain and consequent power of logical thought which enabled primitive man gradually to gain the upper hand of his living enemies and, equally important for his survival, to adapt himself to his environment and avoid the ever threatening destruction of his race by changing climatic conditions. Thus has the "Divinity that shapes our ends" decreed that man, through the power of mind, shall rule the earth. In him today, the muscles of his prehistoric ancestors have lost much of their power, fangs and claws have become rudimentary from disuse, the acuteness of the senses lessened and far exceeded by the comparatively small number of lower animals which still roam at large or are domesticated to his needs and enjoyment. But man's supremacy and very existence have ever been disputed. His enemies from the earliest human records to the present have not been, to any great extent, the lower animals or the forces of nature against which he has long since learned to protect himself. Man himself, throughout history has been and

is today man's greatest enemy. Ignorance, prejudice, distorted thinking, loose living, poverty and filth with their mighty allies—the host of communicable and degenerative diseases—are constantly at war with scientific discoveries and their utilization, with sound thinking and common sense, with justice to individual groups and nations, in short to all the factors which go to make up true human progress. In human beings, with some brilliant exceptions, soundness of mind and body are interdependent. Education, intellectual, moral and social—in the homes, schools and great seats of learning—and the application of discoveries in the field of science are the only means which we possess for the perpetuation and advancement of the human race.

This is neither the time nor place to criticize or deplore the trend of modern higher education with its tendency to cram into the minds of youth smatterings of uncorrelated facts, of which there is not full grasp of power of utilization, with the end result, in most instances, of brain-fag, mental indigestion and loose thinking. Pseudo-intellectuality is a greater menace to human progress than untutored ignorance, for the field of influence of the latter is limited while that of the former spreads like infection throughout wide areas. The day when our teaching institutions shall so rearrange their curricula that their graduates shall be taught to "think straight" and given time in which to do it, will to my mind mark the opening of a new and immensely important epoch in the history of human affairs.

There is no more brilliant and inspiring chapter in the history of human achievement than that which relates to civilized man's struggle for existence against the ravages of the infectious diseases which formerly, in great pandemics especially of plague, cholera and smallpox, took toll of countless millions at the very outposts of civilization. At first stunned and helpless, a mighty Gulliver at the mercy

* Address read before the Twenty fifth Annual Conference of Health Officers and the Eighth Annual Conference of Public Health Nurses, Buffalo, New York, October 12, 1926

A short section has been added to the previous edition describing the Monocular Phorometer of DeZeng collaborating with the author

With the exception of these changes the present edition differs little from the previous one yet its appearance is timely, as it serves again to focus attention upon the ocular motions, a subject after all too vaguely understood

As frankly stated in the preface the work is based upon an hypothesis

"If the hypothesis accounts for every phenomenon connected with the normal and abnormal actions of the ocular muscles, as it seems to do, then it ceases to be an hypothesis and becomes a scientific fact."

With this, as set forth above, fully understood, the work is a valuable contribution to Ophthalmic Literature Yet the reader can hardly refrain from wishing that this "Hypothesis" had been fortified by accounts of experimental work, or at least by references to such, whereby the general tone of the work would have appeared less dogmatic, and more in the spirit of modern investigation and research

H M S

NURSERY GUIDE FOR MOTHERS AND CHILDREN'S NURSES

By LOUIS W SAUER, Ph D, M D Second edition
12mo of 206 pages St Louis, C V Mosby Company,
1926 Cloth, \$2.00

In this book the author presents in simple fashion the general care, nourishment and ills of infants There are chapters on the nursing infant, the premature infant and on artificial feeding Diets are given up to three years of age

A portion of the book discusses some of the common ailments of infants There is also a chapter on the care of the sick baby Here are given directions for many of the therapeutic procedures that are frequently necessary in the nursery Information is given as to first aid in the various accidents that can befall a child

Its completeness and simplicity make it a very good handbook for intelligent mothers and children's nurses

HARRY A NAUMER.

THE CLINICAL INTERPRETATION OF THE WASSERMANN REACTION By ROBERT A KILDUFFE, A.B, A.M, M D Octavo of 203 pages, with illustrations Philadelphia and New York, Lea and Febiger, 1926 Cloth, \$2.50

In this small volume the author points out in a very concise and clear manner the limits and the value of the Wassermann Reaction He betrays an intimate knowledge and broad conception of the practical aspects of a subject about which there has been much discussion In a very able manner he succeeds in establishing a common ground upon which the serologist and the clinician may meet in order to derive the greatest amount of knowledge from the results of the complement fixation test for syphilis for the patient The task that he has assumed was indeed a difficult one, but he has succeeded in arriving at his goal with an admirable result

The book makes very easy reading and is to be very highly recommended, especially to the every day practitioner who wishes to know what the plusses mean in his Wassermann report.

MAX LEDERER.

MODERN METHODS IN THE DIAGNOSIS AND TREATMENT OF HEART DISEASE. By FRANCIS HEATHERLEY, M.B, B.S, F.R.C.S Second Edition 12mo of 269 pages New York, William Wood and Company, 1926 Cloth, \$3.75

The author describes the remarkable changes in our cardiological conceptions which have distinguished recent medical history, and covers a considerable range in his discussion of selected topics The chapter headings are The old and new schools, Abnormalities of the heart beat, Heart failure, Angina pectoris, Blood pressure, Symptoms and signs, Prognosis and treatment, there

is also an Appendix containing Hints to patients on the home treatment of functional disorders of the heart and a List of interesting books The chapter on the old and new schools is particularly good, that on blood pressure is perhaps the least satisfactory Treatment is not gone into extensively, but what little is given is suggestive. The use of digitalis is summed up thus "There is very little scientific evidence to show that it does any good except where increase of heart block is favorable, as in fibrillation and flutter even in fibrillation it does not always act well In some cases toxic effects are produced and the drug has to be discontinued before any showing of the heart has been produced In other cases of auricular fibrillation, even if no toxic effects are produced, no slowing of the heart takes place." The author gives digitalis in moderate doses and has nothing to say of the massive doses which have been recently advocated. He uses strophanthus to supplement digitalis, but apparently considers its action to be like that of digitalis, because he says it should be given in "twice the dose of digitalis," which statement invites criticism The Hints to patients on home treatment of functional disorders of the heart cannot be praised too highly, it is one of the best things of the kind that the reviewer has ever seen The literary style of the book in general is good, though showing carelessness at times which, however, is redeemed by its vivacity The book is easy reading

This book is obviously the work of an experienced and wise and thoroughly up-to-date cardiologist. It is interesting and stimulating as well as instructive. It can be recommended confidently to students of cardiology of all grades

E E C.

THE INTERNATIONAL MEDICAL ANNUAL A Year Book of Treatment and Practitioner's Index Forty-fourth Year, 1926 Octavo of 555 pages with illustrations. New York, William Wood and Company, 1926 Cloth, \$6.00

This volume presents an excellent review of the year's work in medicine and surgery It should prove very useful to the average practitioner It is arranged like a dictionary, so that it takes but a moment to find the information desired Furthermore, the material abstracted is connected into a readable story, another feature that increases its value to the busy practitioner Altogether, the average physician will find the Medical Annual a useful means of keeping in touch with advances in medicine

FREDERIC DAMRAU

EMERGENCY SURGERY The Military Surgery of the World War Adopted to Civil Life By GEORGE DE TARNOWSKY, M.D, F.A.C.S, D.S.M Octavo of 718 pages, with 324 illustrations Philadelphia and New York, Lea and Febiger, 1926 Cloth, \$7.50

In submitting this volume to his colleagues, the author has endeavored to eliminate the barnacles which have clung to many of the text-books on surgery, and to stress those facts which have not only withstood the critical test of time, but also harmonize with our present knowledge of Physiology

The text is divided into several chapters dealing with the Protective forms of nature, Classification of wounds, General treatment of wounds, Technique of emergency surgery, Antiseptics, Bacteriology of wounds, Gas gangrene, Wounds of bloodvessels, Burns, Shock, Injuries of the head, face, and neck, Thorax, abdomen and its contents, Genito-urinary tract, Spinal injuries, Wounds of peripheral nerves, Fractures and dislocations, Amputations, Splints, Roentgenology, and the Medico-Legal aspect of emergency surgery

These chapters are sub-divided into sub-heads where separate conditions are elaborated in very comprehensive manner, accompanied by instructive illustrations

It should prove to be a very valuable reference book to the general surgeon

RALPH F HARLOW.

To draw an exact line between official public health work and the private practice of medicine is likely to prove a more delicate and difficult task which can be accomplished only by the exercise of common sense and a spirit of fair dealing with the rights, duties and prerogatives of those concerned, including the general public

This is the age of preventive medicine. The medical profession is beginning to recognize that fact as well as those who are responsible for teaching the medical sciences. Enlightened public opinion may be more and more counted upon to subscribe to the old adage that "an ounce of prevention is worth a pound of cure." Nevertheless, it can not be denied that a great many people are natural gamblers and willing to take chances even in such matters as have to do with physical and mental health, notwithstanding the fact that the knowledge has been brought to them that with a little loss of time and some inconvenience, many dangers may be avoided which, sooner or later, will cause physical suffering and even lead to premature death.

The first, last, and whole duty of a public health official lies in the field of Preventive Medicine and Hygiene. He can not escape or abrogate that duty to others without breaking his oath of office. This does not mean that all of the work, or indeed a major part of it, can and should be performed solely by official agencies. Those who talk so glibly of the coming of so-called "State Medicine" meaning, I take it, that the State and its constituted political divisions shall assume the whole and direct responsibility for the physical welfare of each individual citizen, need only estimate the approximate cost of such an undertaking and the utter impossibility of recruiting the great army of qualified persons who would be required to perform the work, in order to be convinced of the impracticability of such a plan. In my opinion, it will never be attempted in this country unless or until the general medical profession is unable or unwilling to qualify itself in and practice the principles of preventive medicine with consequent neglect of those who look to it for professional advice. Is there any likelihood of such an occurrence?

Let me call your attention very briefly to certain facts from which enlightening conclusions may be drawn. The teaching of preventive medicine, with any degree of thoroughness, still holds but a minor place in the curriculum of many medical schools, and is practically absent from most, so that a physician who desires to become well-grounded in preventive medicine is obliged to take special courses in that subject, to become a post-graduate student in one of the several schools founded for the

training of sanitarians or work in a public health laboratory. Nevertheless, the adoption and utilization, by the medical profession, of well proven procedures for the prevention of disease which have been urged upon the general public by official and non-official public health agencies, require no special training by any competent and up-to-date physician. How large a part has the general medical profession played in this work so indispensable to the protection of the public health? Let me illustrate. Vaccination against smallpox has long since become to be regarded as a function of public health and school authorities, and as a consequence throughout a large part of this country, vaccination is no longer done as a routine procedure. Were it not for the compulsory vaccination law affecting the larger cities and the power given to the State Commissioner of Health to certify to the existence of outbreaks of smallpox, this State, continually threatened by the disease from the North, South and West, would be constantly over-run by smallpox as are a number of other states of the Union.

Inoculation against typhoid fever, except in time of war, is rapidly coming into disuse even in the case of groups and individuals who, by extensive travel or by abode in places where typhoid prevails, are specially liable to exposure.

The campaign for periodic medical examinations has been under way for several years. It has been advocated by public health authorities, non-official health organizations and insurance companies, and widely endorsed, in principle at least, by the medical profession. Among a few medical groups, in association with unofficial health agencies and notably in the case of at least one medical institution founded frankly as a commercial though laudable enterprise, the campaign up to the present time may be deemed a success, but it would be very difficult to become enthusiastic over the part taken in it by the medical profession as a whole.

Finally, the anti-diphtheria campaign, launched under impressive auspices and widely heralded under the slogan "No diphtheria in New York State by 1930," has been under way for some months. Much excellent publicity material has been scattered broadcast. The State Medical Society and its constituent county societies have generally endorsed it. The State and local departments of health, boards of education, non-official health organizations and insurance companies have done their part. I believe that the results are already evidenced by the remarkable fall that has taken place in the morbidity and mortality rates from diphtheria not only in this State but elsewhere in the country where a similar campaign has been actively carried on. How large a share has the

of invisible enemies, hampered by ignorance and superstition, the people cast the responsibility for their sufferings on an avenging God, prayed and cursed and died. When wave after wave of disease had threatened the very foundations of civilization, it began to dawn upon the consciousness of the more observant members of the medical profession that the spread of plagues was not an act of God nor brought about by climatic conditions nor the influence of astral bodies, but due to exposure of the well to some unknown emanations from the body of diseased persons or articles of food and clothing which had been contaminated by them. In other words, these pioneers in medical science awoke to the first conception of what we know and describe today as infection. As a corollary there followed the first feeble but intelligent efforts of prevention. In spite of the numerous nostrums and procedures, the use of which found many advocates and victims, and the willingness of many people to follow the advice of each newly fashionable quack and charlatan, a human tendency which not a few of their descendants exhibit today, the recognition of the value of personal and civic cleanliness, proper and prompt disposal of the dead, quarantine of sick persons, often too vigorously and brutally carried out, and the destruction by fire of infected material, marked the dawn of preventive medicine. It was a long step from these crude beginnings to what may be regarded as the birth of specific preventive therapy given to an over-burdened world through the power of observation of William Jenner, and a still greater one to that period when by the development of microscopic technique, the bacterial cause of various infections was positively established and logical procedures adopted in all of the more advanced countries to prevent the spread of disease from the sick to the well. The causes of a few diseases having been definitely established, within comparatively few years science developed methods of specific prevention, at first by making it possible to confer upon susceptible persons passive and but temporary immunity against immediately threatening infection as by the use of antitoxin against diphtheria. Very recently the ability to confer active and lasting immunity, not only against diphtheria by the employment of toxin antitoxin but hardly less important against typhoid fever by the inoculation of killed specific organisms, was made available as the result of scientific research. Immunity against many other infections has already been made possible with greater or less success. So much has been written and spoken of these latter day triumphs of medical science that it would be useless for me to do more than to touch upon them at the present time. Their importance to the welfare

of humanity can not be over-estimated and nothing but blind neglect on the part of the people to take advantage of the blessings which science has already bestowed, and will continue to bestow, can prevent the coming of that time, perhaps far distant, when suffering and death from the common infectious diseases, and their remote consequences, will become a rarity and regarded as a disgrace to a civilized community.

The establishment of official public health work is of comparatively recent date. In this country, although it has made vast strides during the past decade, it is but in its infancy. That the protection of life and health is a governmental function, and one of its most sacred obligations, has long since been generally recognized, and thus has come about the custom of recruiting from the ranks, mainly of those learned in the medical sciences and sanitation, individuals who shall direct and supervise measures for the protection of the public health.

The importance of the work of departments and boards of health—national, State and local—is being daily recognized, the personnel better qualified to perform its various duties, and funds for the support of the work, while yet in many cases pitifully inadequate, notably increased. The sphere of activities of official public health is constantly widening with the inevitable result that the question becomes more and more insistent as to what constitutes the legitimate field of official public health work, first in so far as it seems to enroach upon the domain of other branches of government and second on the private practice of medicine. Without a great deal of mental effort, it may be shown that practically every human activity is directly or remotely related to public health, and there is today an unquestioned tendency to over-load public health service with functions which, at the present time at least, it is not equipped to exercise, while on the other hand, notably in the case of the federal government but also in States and local communities, indisputable public health functions are assigned to departments, bureaus and agents of government which, only by the wildest stretch of imagination, logically belong to them and which, in many instances, they are totally unable or unwilling to perform.

In this State we are about to conduct our public affairs under a reorganized and simplified form of government. Time and experience will unquestionably bring about many changes in detail of the plan proposed. With wise leadership and public support, it is to be hoped that a very definite understanding may be arrived at and embodied in law as to what does and what does not constitute an official duty of the health authorities.

not exactly a clear one in the minds of many surgeons unless it has fallen to their lot to have done considerable cadaver work previous to entering upon their active surgical career. However, very definite knowledge of this space is necessary to the surgeon who attempts operative procedures in this condition. The most simple, though not strictly anatomical description of this space, is by Barnard². He considers this space as being divided into intraperitoneal and extraperitoneal portions. The intraperitoneal portion is subdivided into four separate and distinct spaces by the falciform, coronary and right and left lateral ligaments of the liver. This gives arbitrarily, a right and left anterior space and a right and left posterior space in the intraperitoneal portion. The extraperitoneal portion consists of two separate areas, the right between the uncovered layers of the coronary ligament and the left above the left kidney.

There are many different etiological factors in subdiaphragmatic abscess. About two-thirds of the abscesses are due to infection from intraperitoneal viscera, the remainder are due to extension from extraperitoneal organs or from more distant sources. Infection of the subdiaphragmatic space may take place by direct extension, by lymphatics or by blood vessels. If is questionable if subdiaphragmatic abscess does result primarily from infection through the portal vein which admittedly may cause hepatic abscess. The stomach, duodenum, liver, gall bladder and appendix are the abdominal viscera in which infection most commonly arises. Of these organs the stomach and appendix are the most frequent offenders. A study of statistics of a quarter of a century ago shows that the stomach was most commonly the primary focus but today with the refinements of modern diagnosis of gastric lesions, the stomach as a focus has fallen far behind the appendix. The most common source of infection without the peritoneum is the kidney. Even distant abscesses or infections result occasionally in the formation of pus beneath the diaphragm. The organisms most commonly found in subdiaphragmatic abscesses are colon bacilli, streptococci or anerobes.

The pathological findings in cases of subphrenic abscess are varied. Primarily they depend upon the source of the infection, the infective organism, the duration of the abscess and its location. The abscesses may be single or multiple. They are commonly trabeculated or have partitions which often results in inadequate drainage from operation. It is not uncommon to find a series of communicating abscesses connected by small sinuses. Following infection of the subphrenic space, two or three weeks must elapse before definite abscess formation takes place. Gas is found in the abscess quite frequently, rarely the abscess contains nothing but gas. The contents of the abscess depends upon

its location and duration. Essentially the products of liquefaction of broken down tissues are present. If the liver is involved, then destroyed liver tissue may be encountered. When the abscess is the result of a rupture of an ulcer of the stomach or duodenum, a sinus may exist between the two but this is not the rule, for most perforations close with the development of the inflammatory reaction incident to the formation of the abscess. Subdiaphragmatic abscesses occur more commonly upon the right side than the left, bilateral abscesses are rare.

The symptoms of subphrenic abscess vary with its location, extent, cause and duration, they are frequently overshadowed by the symptoms of the primary condition. As subphrenic abscess is so commonly the result of intraperitoneal infection, its presence should be suspected with the development of signs of extension of infection, especially when these follow operative procedures. The onset is often insidious with no localizing signs at all—the patient simply continues to lose weight and strength without apparent cause. The onset may be long delayed after operation for the primary condition. Eisendrath³ cites a case in which symptoms were delayed for one year after appendectomy. On the other hand, the onset may be sudden with rigor and severe pain. Fever is perhaps one of the most characteristic symptoms of subdiaphragmatic abscess. It is of the church steeple type showing many variations. Chills usually occur at some stage in the disease. The pulse generally is in keeping with the temperature as is the respiratory rate but the latter may be normal.

Pain is commonly complained of at the costal margin with radiation to the back. Tenderness over the area is likewise a common finding. It may be absent however. If the location of the abscess is superficial, bulging of the chest wall may be noted. This is present in about sixty per cent of the cases. In some instances there may be oedema of the overlying soft parts with dilation of the superficial veins.

Cough likewise occurs frequently and is of the catchy diaphragmatic type. It is a very distressing symptom. Hiccough and vomiting occur in about half of the cases at some stage in the disease. As the disease progresses, loss of weight and anemia ensue. In occasional instances, the abscess ruptures into a bronchus with profuse fetid expectoration. Ullman and Levy⁴ cite a case in which this occurred and the case reported below also illustrates this complication.

Because of the elevation of the diaphragm on the side of the abscess with compression of the lung, chest examination often reveals signs similar to empyema or a basal pneumonia. In fact, subphrenic abscess is frequently mistaken for one or the other of these conditions. Respiratory movements of the affected side are usually restricted. The liver is frequently pushed down-

general medical profession taken in this work? From official reports received by the State Department of Health from district State health officers and local health officers and innumerable personal interviews with practicing physicians, I am prepared to state without fear of contradiction that, up to the present time, the great majority of the medical profession has done little or nothing to bring about immunization against diphtheria among their private patients. As I pointed out in an address before the State Medical Society at its last meeting, in spite of the fact that this campaign has been designated as one of five years' duration, as a matter of fact it is one which must be carried on indefinitely or for many years to come if the State is to be kept free or practically free from diphtheria. For that reason, it is a vital necessity that the medical profession take an active part in its conduct. It is hardly conceivable that the general immunization of children of pre-school age can be achieved, to any great degree, unless general practitioners make themselves responsible for immunization among their own patients, or such of them as are willing to have it done. I have tried faithfully to determine the cause, or causes, why the general practitioner has seemed to show indifference or hesitancy to take an active part in health campaigns and utilize, as a matter of routine, established preventive procedures. Many reasons have been given but the commonest, and I fear the most difficult to overcome, is the hesitancy and delicacy on the part of our best practitioners to take any action among their patients which would seem to leave them open to the charge of commercialism by seeking to increase their practice. There is further a question of so-called medical ethics which apparently deters many physicians from sending for their patients, notwithstanding the fact that they should be seen and advised as to conditions which require medical attention. This attitude of mind it not to be sneered at nor lightly cast aside, but I submit that it must be abandoned from sheer necessity if the medical profession is to do its full share in the

work of preventive medicine, and I firmly believe that the general practitioner is not doing his full duty to his patients if he does not keep constantly in touch with their physical condition, growth, development and protection against infection. This can not be done unless physicians in general will follow the example of a few of their number who regularly adopt the practice of sending for their patients at such intervals as they deem necessary for physical examination, regulation of the diet, habits of living, vaccination against smallpox, typhoid fever, when deemed necessary, and immunization against diphtheria, and I venture to predict that by so doing, physicians who have the confidence of their patients will find that confidence increased and their reputation for ethical practice untarnished. The gratitude of those who will appreciate the interest shown in their condition and the results which are certain to be evident in many cases, will more than outbalance the opinion of the few petty-minded individuals who will see nothing but ulterior motives and selfishness.

In conclusion, I have tried to show briefly, and I fear most inaccurately, that the human race, if it is to survive and go forward, must be protected against the ravages of disease in so far as that is possible. Only in the ranks of the medical profession, whether the work be conducted in an official or private capacity, and with the aid and cooperation of all unofficial organizations that have anything of value to offer and the great body of enlightened citizens, will such protection be forthcoming. The supervision of morals, except in so far as they involve personal and public health, may well be left to spiritual advisors, parents and guardians, but the responsibility for the present and future physical welfare of our race must be fully shared by all those who by professional calling and scientific knowledge are alone capable of assuming it. In this work there is glory, honor and satisfaction enough for all. May every one do his full share to the limit of his ability and opportunities.

SUBDIAPHRAGMATIC ABSCESS

Report of a Case with Unusual Termination

By ARTHUR M. DICKINSON, M D, F A C S, ALBANY, N Y

THE collection of pus beneath the diaphragm and in contact with it is known as subdiaphragmatic or subphrenic abscess. This condition is not to be confused with pyelophlebitis and hepatic abscess which have recently been so well discussed by Elason.¹

Barlow in 1845 was the first to recognize this condition in a living patient and describe his findings. Previous to this time, cases of subphrenic abscess had only been diagnosed at post-mortem examinations. Operation was first performed for subphrenic abscess in 1879 by Volkman.

The picture of the subdiaphragmatic space is

¹ Presented in abstract before the Albany County Medical Society February 9, 1926

were permitted by mouth. Two days later the enterostomy tube was removed as it had ceased to function and good results were obtained with enemata. There was considerable drainage by the cigarette drain which was being removed little by little until it was completely out on the eighth postoperative day. By the tenth postoperative day the temperature was not rising any higher than 100. The general condition of the patient was considered good, the wound was healing and the patient taking nourishment well. On the seventeenth postoperative day the temperature rose to 103. This was thought to be due to wound infection or an abscess in the pelvis. The temperature remained elevated and on the twentieth day definite resistance was noted at the upper angle of the incision. Attempts were made to re-open the wound in this location but without success. At this time the white blood count was 10,400. Two days later there was profuse drainage from the lower angle of the wound and with this development, the resistance at the upper angle of the wound disappeared but the temperature did not fall. Another white count was reported as 11,500.

By the thirtieth postoperative day, however, the temperature ranged between 99 and 100 and there was apparently nothing to worry about. Three days later the temperature was elevated to 103 and remained high. During this period repeated chest and abdominal examinations had been made but it was not until the thirty-fifth day that an area of dullness was noted at the base of the right lung, posteriorly. The leucocyte count at this time was 9,200. X-rays the next day revealed a probable subphrenic abscess on the right side. (See Plate 1). At this time aspiration with long needles of large calibre was tried in the 8th, 9th and 10th interspaces in varying locations from the anterior axillary line to the scapular line. The abscess could not be located. On the thirty-eighth day another blood count was done with the following report—leucocytes 14,850, erythrocytes 3,353,000, hemoglobin 76 per cent. Blood cultures taken at this time showed no growth after seventy-two hours. For five days after the unsuccessful attempts at aspiration, the temperature remained between 99 and 100 but on the forty-second day it rose to 103 again. The chest signs became more prominent. The area of dullness at the right base increased in size, increased vocal resonance was noted with slightly prolonged high pitched expiration and occasional fine rales. During this period, attacks of coughing became very marked, expectoration was profuse and vomiting often followed the fits of coughing. No pain was complained of at any time. Nevertheless the condition of the patient was becoming progressively worse due to high temperature, toxemia and lack of nourishment. On the forty-fourth postoperative day further

PLATE I—Note elevation of diaphragm on the right side, clear pleural cavity, absence of fluid in costophrenic angles, apparent cupping of diaphragm.

X-ray examination was made to aid in localization of the abscess. The inability to locate the abscess with repeated needlings was the reason for delay in operation. In spite of these failures in locating the abscess, it was deemed wise to proceed with operation as a method of last resort.

Two days later, under gas and oxygen anesthesia, aspiration was again performed with negative results. The tenth rib on the right side was then exposed and about 10 cm. of it resected, beginning at the posterior axillary line and extending forward. The pleura was then incised and as adhesions between its two layers were present, the diaphragm was opened. The abscess was diligently searched for with finger, clamp and aspirating needle but could not be located. After a half hour had been consumed in this unsuccessful hunt for the abscess, it was deemed wise not to inflict further insult upon the patient and the wound was closed.

The shock of operation was considerable but was very successfully treated with glucose and insulin. Thirty-six hours after operation the patient developed a severe toxic nephritis. The output of urine fell to less than ten ounces in twenty-four hours and the urine was loaded with blood cells and casts. Under treatment this condition was relieved but not until two weeks before the patient's discharge from hospital was the urine free from all evidence of renal irritation. Following operation the general condition of the patient improved. There was less cough but the temperature remained between 101 and 102. On

ward on the side of the abscess. The leucocyte count in subdiaphragmatic abscess varies. It commonly shows an increase but there may be an actual leucopenia in patients with lowered resistance.

The X-ray is probably the most valuable aid in diagnosing this condition. Lewald⁵ states "In view of the many cases recently reported of difficulty encountered in the diagnosis of subphrenic abscess, resulting in delayed operative procedures, it appears desirable to stress the roentgen ray diagnosis of this condition." He recommends several pictures in different positions for comparative purposes and study with the fluoroscope. The diaphragm, on the affected side is usually elevated and may show some cupping. The costophrenic angle is not obliterated as it is in pleural effusions. A gas bubble may be observed between the liver and diaphragm. In the absence of a gas bubble and a definite fluid level, the X-ray diagnosis is more difficult. Cottle⁶ describes a case in which the diagnosis was in dispute for three and one-half months.

The principal conditions with which subphrenic abscess is liable to be confused are pneumonia and empyema. Usually these can be eliminated by careful history taking, a searching physical examination and a co-operating radiographer.

The use of the aspirating needle for diagnosis and as an aid to localization of the abscess is not without dangers. It is very easy to pass through the pleural cavity and diaphragm and upon withdrawing the needle, infection is carried into the pleural sac. Also unless one is absolutely sure of just where the point of the needle is, it is unsafe to attempt differentiation between empyema and subphrenic abscess by this means. In some instances it is impossible to locate the abscess with a needle even after you are aware of its existence.

The prognosis in cases of subdiaphragmatic abscess should be very guarded. At least eighty per cent of patients not operated upon die. About twenty-five per cent of those operated upon and have the abscesses drained, also die. This gives a mortality rate in all cases of over fifty per cent.

Treatment consists of surgical drainage of the abscess. This is not quite as simple as it sounds. The first difficulty is that of locating the abscess and the second is the choice of the safest route for approach and drainage of the abscess. Depending upon the location of the abscess, the method of approach will vary. There are two general routes, one through the chest and the other through the abdomen. The danger of spreading infection to the pleura or peritoneum is great. Mechanically it is much easier to prevent soiling the pleura than the peritoneum and for this reason most operators prefer the transpleural approach to the abscess. In abscesses of the left anterior space approach and drainage must be through the peritoneum. This is also

true in some instances of abscess of the posterior space on the left side.

Probably the safest method of approach through the pleural cavity is that described by Lockwood⁷. The incision is located in the 9th, 10th or 11th interspace over the area of bulging. If this is not present, the incision is started at the posterior axillary line and carried forward. By undermining the skin it is possible to suture this to the diaphragm later on, thus walling off muscle and fascial planes from infection. The ribs are spread (rarely is resection necessary) and the parietal pleura sutured to the diaphragm thus walling off the pleural cavity. The skin is then sutured over the muscle as noted above. If conditions warrant it, after smearing over the suture lines with sterile vaseline, the abscess may be opened through the diaphragm at once. In some instances it may be wiser to wait twenty-four or forty-eight hours before proceeding with this step. After the abscess is opened, one must avoid breaking down adhesions which may be acting as a barrier to extension of infection to the greater peritoneal cavity. As the abscesses are frequently multiple or sacculated, one must make sure that every recess is cleaned out thoroughly. Drainage in the form of a two way tube is inserted and the wound loosely packed, so that it will heal by granulation.

REPORT OF CASE

Mr C B P, age 22, entered the Memorial Hospital on Sept 14, 1925, with symptoms of acute appendicitis, but refused operation until the following day. At operation it was found that the appendix was gangrenous and walled off quite well. There was no free purulent exudate. The appendix was located behind the cecum and was placed rather high up and more toward the midline than usual. Ligation of the appendix was done and it was removed with cautery. The stump was not sewn over. As this was the type of case in which the subsequent development of an ileus might be anticipated, a loop of ileum was picked up and a tube enterostomy was done by burying the tube in a fold of gut. The intestine was then dropped back into the peritoneal cavity. A cigarette drain was inserted in the right side of the pelvis and the incision closed by layer suture.

Postoperative treatment consisted of replacement of fluid loss by rectal, subcutaneous and intravenous routes, modified Fowler position and plenty of morphia. On the day following operation, the abdomen was soft and the enterostomy tube was draining well. The temperature ranged between 101 and 103. For the following two days, the abdomen was hard and distended with the temperature still elevated. By the fourth day the abdomen was much softer and only moderately distended. On the fifth day the condition of the patient was so satisfactory that fluids

THE MEASUREMENT OF INTRACRANIAL PRESSURE—VENTRICULOMETRY*

By K WINFIELD NEY, M.D., NEW YORK CITY

IN the experience of most clinicians, the determination of increased intracranial pressure often resolves itself into a rather vague and uncertain affair. The general effects of increased pressure, namely choked disk, headache and vomiting have been the only signs upon which it has been possible to establish a diagnosis. These clinical signs however, particularly in early cases, are often so poorly developed that the clinician is compelled to resort to rather prolonged and often hazardous observation before their adequate development will permit him to venture a diagnosis of increased pressure with that degree of certainty which will justify a recommendation of radical procedures. So often indeed is a careful examination of the eye grounds neglected that the unhappy victim of an increased intracranial pressure is subjected for months and occasionally years to various medical and surgical procedures directed toward the alleviation of headache and vomiting, without appreciation of the underlying cause. Occasionally too, the typical picture of choked disk is not present, and in its absence the advent of persistent headache is very likely to be attributed to gastrointestinal disorders, accessory sinus disease, eye strain, migraine, etc. A failure to recognize an increase of intracranial pressure is indeed a catastrophe to the patient, and the delay is often responsible for the development of advanced cerebral disturbance—recognized only when it has become a terminal affair.

In every branch of surgery, our failures may be often attributed to delayed diagnosis, permitting pathologic processes to advance to that degree of anatomic destruction which precludes sufficient function to sustain efficiency, or even life. It is a common experience to see patients with advanced degrees of intracranial pressure who have sought relief from headache, vomiting and visual disturbances for many months before the attention of the medical advisers has been directed to the central nervous system by the advent of paralysis, convulsions or blindness. In many instances, these unfortunate occurrences of delayed recognition of increased pressure have not been due to the lack of appreciation of the condition on the part of the clinician, but solely to the fact that there existed no certain means of determining an increase of intracranial pressure, because the usual signs upon which such a diagnosis could be made were too ill-defined to arrive at a conclusion.

Spinal Puncture and Ventricular Puncture
The advent of the spinal mercurial manometer has served as a valuable adjunct to lumbar puncture and has proved of inestimable value in the diagnosis of certain pressure increasing lesions—particularly head trauma. The occasional fatality following lumbar puncture when attempted in certain types of increased intracranial pressure, has caused many clinicians to hesitate before venturing a spinal tap in chronic increases of pressure. The danger in spinal puncture is due largely to the fact that in marked degrees of intracranial pressure the tonsils of the cerebellum become herniated in the foramen magnum, resulting in strangulation of the medulla, when the supporting fluid of the spinal canal has been released by lumbar puncture. Furthermore, we have repeatedly demonstrated that the pressure readings of spinal puncture may vary greatly from the readings following tap of the ventricles.

Measurement of Intracranial Pressure
While doing a series of air injections for ventriculography in suspected brain tumor cases, we were impressed by the force with which the ventricular fluid was projected into the syringe connecting the ventricular needle. As a result, we arranged an attachment by which the needle could be easily connected with a mercurial spinal manometer, making it possible to accurately measure the intraventricular pressure, thereby determining the degree of intracranial pressure. The procedure of measuring intraventricular pressure we have termed "ventriculometry," and this, combined with Dandy's method of ventriculography, in which air is injected into the ventricles and their size and shape determined by roentgenological examination, has served as an admirable supplement to careful neurologic examinations and has made possible a diagnosis in many obscure conditions where clinical neurology alone, without these aids, had been seriously handicapped.

The value of ventriculometry lies not only in definitely determining an increase of intracranial pressure, but also in accurately measuring the degree of that pressure. In our clinic, this has become a routine procedure in all cases where the symptomatology suggests a deviation from normal intracranial pressure. We early demonstrated that inhalation anesthesia markedly increases intracranial pressure, and found that in order to obtain accurate pressure readings it is necessary to make the ventricular tap under local anesthesia, with the patient lying on his side, with the midline of the head

* Read at the Annual Meeting of the Medical Society of the State of New York, at New York, March 30 1926

the ninth day after this operation, the wound of the chest wall suddenly opened up and about one pint of pus was evacuated. Drainage now continued from the wound. Cough was increased at times and the sputum contained foul-smelling green pus, which showed upon culture streptococcus vididans as did cultures from the abscess. From this time on, the temperature curve gradually fell and the improvement in the patient's general condition took place. He was eating and sleeping well but still had occasional bouts of coughing which would often be preceded by an elevation of the temperature. By the third week after the second operation, the patient was taking fresh air treatment out-of-doors and the temperature was not rising above 99. X-ray examination at this time showed conditions very much improved. (See Plate 2)

PLATE II—Note improvement as compared with Plate I

By the seventy-third day the patient's condition was considered good. Both operative wounds were healed. The area of dullness at the base of the right lung was much smaller and breath sounds appeared normal. There was noted some limitation of expansion at the base however. The finger nails of the patient were slightly blue but there was no clubbing of the tips of the fingers. The pulse rate was 72, the temperature 99, the respirations 20. The patient

was strong physically, he walked about, he ate and slept well but still had attacks of productive coughing although the sputum was no longer purulent. He was discharged from hospital on the seventy-fourth day and placed under care of his family physician.

A report from the family physician two months after discharge of the patient stated that the patient's temperature had been absolutely normal for over two weeks. There was still some cough, especially upon retiring, but little expectoration. A marked gain in weight and strength had occurred. A letter from the patient four months after discharge from hospital was very illuminating. The patient reported that he had not had a coughing spell for over four weeks. He was still gaining in weight and strength, could run up and down stairs, had no pain at all. All he noted was lack of endurance. He felt that he was cured.

SUMMARY

The case reported above emphasizes several important points relative to subdiaphragmatic abscess.

1 The abscess was secondary to a ruptured appendix located high up in the abdomen.

2 The onset of the abscess was insidious, being recognized only after repeated chest examinations.

3 The variance of the leucocyte count in this condition.

4 The difficulty of locating the abscess in some instances.

5 The value of the X-ray in diagnosis.

6 The development of a fistulous communication between the subphrenic abscess and the lung which was a very important factor in the recovery of this patient.

the blood pressure has risen, so that under such conditions the relief of an increased intracranial pressure has been followed by an elevation of blood pressure. In acute head traumas, an elevation of blood pressure is often observed during the effort of medullary compensation, this increase apparently takes place only in the primary reactions of acute pressure changes.

Pressure Increasing Lesions Cerebral tumors rarely produce general pressure symptoms before they have attained considerable size, and often large tumors are tolerated without producing visual changes, gastric disturbance, or discomfort. Certain tumors, however, because of their location, even though small in size, may produce hydrocephalus, with general pressure symptoms, or localized pressure on important cerebral centers, creating profound focal disturbance. Tumors of this nature, however, because of interference with important centers, receive more early recognition than large tumors occupying the so-called "silent areas." In our experience, the majority of brain tumors involving silent areas, and coming to operation because of general pressure signs or convulsive phenomena, register an intracranial pressure of 25 to 35 mm Hg. Several cerebral cysts, however, though producing some deformity of the ventricles, have, particularly when associated with convulsive phenomena, shown only moderate increase of pressure—10 to 14 mm Hg. Other cysts have shown an increase comparable to the average silent tumor. Pressure readings do not serve to differentiate between endotheliomas and gliomas, both of which seem to produce about the same degree of pressure elevation.

Hydrocephalus The highest pressure readings found in this series, with one exception (brain abscess with general encephalitis) have been found in the so-called "communicating" type of hydrocephalus. In these cases, the pressure has varied from 40 to 60 mm Hg. These communicating types of hydrocephalus are usually due to inflammatory or tumor obstruction about the brain stem blocking the escape of cerebrospinal fluid from the posterior fossa to the cerebral subarachnoid spaces. There is, however, one type of communicating hydrocephalus, due to syphilis, where the blocking is less complete and the elevation of pressure is comparatively low—14 to 20 mm Hg, and apparently more or less intermittent, the periods of pressure elevations usually being attended by acute psychomotor manifestations—often rapidly relieved by tapping the ventricle. Congenital types of hydrocephalus, due to occlusions of the iter, probably because of the decompressing effect of cranial enlargement, rarely show the high pressure changes observed in the communicating types of the adult. These congenital (non-communicating) types of hydrocephalus may

exhibit various degrees of intracranial pressure (8 to 40 mm Hg). We have observed a few cases with greatly enlarged heads, showing a normal pressure, these cases had been attended with such a degree of dilatation that the ventricles had probably ruptured into the cisterna through the thin cerebral cortex at some point, producing spontaneous relief. Hydrocephalus induced by cerebral or posterior fossa tumors rarely incite degrees of pressure above 30 mm Hg.

Brain Abscess and Sinus Thrombosis Cerebral abscesses produce about the same degree of pressure elevation as cerebral tumors, and both may be accurately localized by ventriculography. In cerebellar abscesses of otitic origin, the tendency is to produce higher degrees of pressure than cerebellar tumors, because of a frequently associated sinus thrombosis. A lateral sinus thrombosis will usually increase intracranial pressure about 8 mm Hg, its presence may be readily determined during ventriculometry by compression of the jugular veins. Compression of a normal jugular vein will elevate the pressure about 8 mm Hg. A compression of either jugular vein which fails to elevate intracranial pressure indicates a corresponding lateral sinus occlusion.

In cerebellar abscesses the pressure inciting factors are threefold (1) abscess, (2) hydrocephalus, produced by posterior fossa pressure, (3) lateral sinus thrombosis in cases of abscess developing from otogenic infections and spreading to the cerebellum through the medium of an infected sinus. The abscess is usually located on the side of the thrombosed sinus, which may be readily determined by differential pressure readings during jugular compression.

Trauma and Infections The cerebrospinal fluid gains exit from the subarachnoid spaces of the cerebral cortex by filtration through the arachnoidal villae into the cerebral veins and venous sinuses. These arachnoidal villae may become occluded by an excess of cells in the cerebrospinal fluid, producing moderate elevation of pressure. Cerebral injuries associated with mild degrees of hemorrhage in the subarachnoid spaces will produce pressure symptoms due to arachnoidal villae blocks, comparable to those produced by the formation of relatively large hematomas, but are usually not attended with focal symptoms. The arachnoidal villae, acting as filters to the cerebrospinal fluid, collect the circulating red or white cells as the fluid filters through and interfere with further filtration, producing an excess of fluid on the cortex—a condition not to be confused with true cerebral oedema. Decompression and repeated spinal punctures tend to relieve the fluid pressure caused by arachnoidal villae blocking. When neglected, however, and the pressure is

(corresponding to the longitudinal sinus) on a plane with the axis of the spinal canal. The readings should be made with the patient quiet and the mouth open, which seems to prevent straining. Many patients who have experienced both ventricular and spinal taps are emphatic in their assertion that the ventricular tap was less painful, and certainly in the presence of an increased intracranial pressure, ventricular puncture is decidedly less dangerous. Though the procedure is quite simple, an accurate technic must be mastered and maintained in doing ventriculometry, and should not be attempted by one who is unfamiliar with all the technical points.

Pressure in Different Lesions Up to the present time we have made 128 ventriculometric readings. We assume from this series that the normal intraventricular pressure is approximately the same as the pressure of the spinal fluid, namely, about 8 mm Hg. We have found pressures ranging from zero to 65 mm Hg. The lower pressures—cerebrospinal fluid hypotension—are to be found mostly in the after effects of cerebral vascular thrombosis with cerebral atrophy, and certain types of epilepsy and dementia praecox. Higher types of pressure encountered in this series have been encephalitis, as high as 65 mm Hg, the so-called communicating type of hydrocephalus in adults, 40 to 60 mm Hg, cerebral tumors and abscesses, 25 to 35 mm Hg, hydrocephalus, congenital, 8 to 40 mm Hg, hydrocephalus, due to posterior fossa tumors, 15 to 30 mm Hg, chronic brain injuries showing post-traumatic neuroses, 16 to 24 mm Hg. The range of pressure increasing lesions of this series represents the minimum and maximum readings we have found in each type of case, though doubtless further experience will reveal that these lesions may even show a wider range of pressure.

Reactions to Pressure Changes The measurement of intracranial pressure has demonstrated that undoubtedly cerebral (cortical) activity is greatly influenced by intracranial pressure, and we have frequently noted that mild increases—14 to 24 mm Hg—are almost invariably attended with general nervousness, restlessness, irritability, tremors and exaggerated reflexes. In acute conditions, as the pressure increases, the irritability and restlessness progress to delirium and finally to stupor, coma and death. In chronic conditions, however, with slowly increasing pressure, patients seem to lose their irritability, restlessness, exaggerated reflexes and tremors, showing mental confusion and sluggishness accompanied by headache, vomiting and general weakness, with visual disturbances, emaciation, loss of strength and death. In acute elevations of pressure the trend of symptoms is rapidly progressive with the increase of pressure, in chronic elevations, the

irritable symptoms are usually replaced by sluggish reactions. The sluggish reactions of the impaired nervous system, due to increased pressure, are decidedly less conspicuous in acute conditions because of rapid progression. In cerebral hypotension, the reactions are less constant and the cerebral cortex here seems to show a tendency toward apathy.

Eye Grounds in Intracranial Pressure A comparative study of the eye grounds and ventriculometric readings seems to indicate that in both acute and chronic increases of intracranial pressure the earliest changes are to be seen in the retinal vessels, principally in the veins which first become congested (darker in color), and finally engorged and tortuous. From the stage of congestion, the veins gradually dilate until they become several times the size of the arteries, with the congestion and engorgement of the veins, the disks become increasingly heightened in color. In chronic increases of intracranial pressure, the occurrence of oedema ultimately elevates the disk edges, producing typical papilloedema or choked disk. As the venous engorgement becomes intense, it is common to find retinal hemorrhages. When the pressure in or upon the optic nerve becomes sufficiently great, degeneration of nerve fibers and atrophy supervene, the pressure within the sheath of the nerve is relieved by the degeneration of fibers (loss of substance), the oedema and venous engorgement slowly subside and the blurred red disk finally assumes the appearance of atrophy, becoming pearl white, and showing a very marked contrast between the nerve head and the pink color of the surrounding eye grounds. Apparently many oculists fail to appreciate the significance of dilated, congested or engorged veins, and await the development of definite papilloedema before considering the possibility of increased intracranial pressure.

In acute brain injuries, the engorgement of the retinal veins and the resulting tortuosity and dilatation rarely progress to true papilloedema, the acute pressure usually producing death before medullary compensatory changes can supervene, as occurs in the more slowly progressive elevations of pressure.

Intracranial Pressure and Blood Pressure A comparative study of cases in this series seems to indicate that intracranial pressure has but little influence upon blood pressure. In a number of instances where the systolic pressure has been above 200 we have found a relatively low intracranial pressure, and in the majority of cases with high intracranial pressure, the systolic pressure has been below 110. In most of the latter, the activities of the individual had been greatly impaired through headache and vomiting, but with the relief of intracranial pressure and the resumption of normal activities,

RECORDING PROGRESS IN CIVIC MEDICINE

The last few issues of this JOURNAL have recorded many items of progress in the practice of civic medicine and public health in New York State. Medical societies all over the country are confronted with the demand of the people for defense against preventable diseases. Abstractly, physicians realize their duty to provide that defense along every possible line, but concretely nearly every individual physician excuses himself from seeking to practice preventive medicine. The past year or two has witnessed a growth of consciousness among family doctors that each

individual doctor has a grave responsibility toward of the members of the families in his own practice, and impersonally toward the community. The discharge of that responsibility is largely through the county medical societies.

A spontaneous movement for the active practice of civic medicine and public health by county medical societies has developed in New York State to such an extent that its record is well worth studying. The evidence is contained largely in the accounts of the District Branch meetings.

allowed to continue, many of the arachnoidal villae may become permanently occluded, leading to chronic increase of intracranial pressure, which is usually manifested by headache, nervousness, irritability, inability to concentrate tremors and exaggerated reflexes—post-traumatic neurosis. The same group of symptoms may follow infectious processes, which increase the number of cells circulating in the cerebrospinal fluid, and also produce arachnoidal villae blocks. In these types of post-traumatic or post-infective neuroses, the intracranial pressure usually registers between 16 and 24 mm Hg.

The importance of early recognition of increased intracranial pressure cannot be over-emphasized. The frequency with which neurologic surgeons observe the ill effects of delayed recognition of intracranial pressure and the disastrous results following many attempts at nasal accessory sinus surgery for the relief of papilloedema, lead us to be very emphatic in the statement that no operative procedure upon the nasal accessory sinuses for the relief of papilloedema can be considered justifiable until an increased intracranial pressure has been definitely excluded. Undoubtedly, the measurement of intracranial pressure will reveal pressure alterations in other diseases of the central nervous system than those considered in this report. Certainly, in suspected pressure increasing

lesions, the measurement of pressure will assist in confirming diagnosis, and serve to differentiate those lesions which exhibit limited degrees of pressure elevation.

CONCLUSIONS

- (1) Ventriculometry consists in measuring the ventricular pressure, thus determining the degree of intracranial pressure.
- (2) Tapping of the posterior horns of the lateral ventricle for pressure determination is a safe procedure, with considerably less attending discomforts than spinal puncture.
- (3) Inhalation anesthesia greatly increases intracranial pressure, hence ventriculometry will furnish reliable readings only when done under local anesthesia.
- (4) The determination of the degree of intracranial pressure provides a valuable differential diagnostic aid in pressure increasing lesions.
- (5) Persistent vomiting, headache, visual disturbance, or decreased or augmented psychomotor manifestations should always suggest the possibility of abnormal intracranial pressure changes.
- (6) Operations on the nasal accessory sinuses for papilloedema are never justified until the absence of an increased intracranial pressure has been definitely determined.

RECENT STUDIES OF GONOCOCCUS VAGINITIS OF INFANTS*

By DR E J WYNKOOP AND DR. EDGAR O BOGGS, SYRACUSE, N Y

From the Hazard Memorial Laboratory, Syracuse Memorial Hospital.

At the 1923 meeting of this society, a preliminary report on "The Occurrence of Gonococci Vaginitis in the New-born" was read and subsequently published in the New York State Medical Journal for October, 1923. This work was undertaken as a part of the effort to ascertain the source of an epidemic of gonococcal valvo-vaginitis which broke out in the children's wards of Syracuse Memorial Hospital. The present report is simply a continuation of the previous work which consisted of the routine examination of vaginal smears taken on the first, fourth and thirteenth days after birth. We wish to add to the 163 cases published, 435 additional. These smears were examined for Gram negative intracellular diplococci, and the presence or absence of polymorphonuclear leukocytes and the form and staining qualities of the prevailing type of organism.

In this second series as in the first, not a smear showed Gram negative intracellular diplococci

Thirty-five (35) per cent showed no polys at any of the three examinations, 16 per cent showed polys on the first day, while they were present in 58 per cent on the 13th day. The type of bacteria present seemed to determine to some extent their presence or absence, the Gram positive cocci being associated in a considerable number of cases, with large number of polymorphonuclear leukocytes. On the other hand the Gram positive bacilli were usually the predominating organisms in those cases showing no pus cells. Clinically, the cases showing large numbers of pus cells differed in no respect from those which had negative findings as to pus cells and bacteria. During the time these studies were going on four (4) cases of gonorrheal ophthalmia were discovered, none of which developed a g c vaginitis.

Conclusions (1) The occurrence of Gonococci Vaginitis in the New-born must be at least extremely rare. (2) The occurrence of pus cells in the vaginal secretions seems to be of little clinical significance.

* Read at the Annual Meeting of the Medical Society of the State of New York, at New York, March 31, 1926.

the sixty county societies are supreme. However, it is fortunate that the question of supremacy has never come up to disturb the harmony that has always existed between the State Society and its component county societies.

The following is an attempt to index the items in which the Medical Society of the State of New York is of value to its members.

A As a part of the National body of physicians, The American Medical Association

1 Privilege of becoming a fellow of the A. M. A.

2 Representation in the governing body of the A. M. A.

3 Participation in all that the A. M. A. stands for, such as ethics, standards of medical practice, studies of hospitals and medical schools, investigation of drugs and new remedies, and of quacks and their remedies, and as a general clearing house of medical information

B To County Medical Societies

1 The maintenance of a central office for records of the members and officers of county societies

2 Field service and advice of the State officers, especially the executive officer

3 Assistance in graduate education and other activities of the county societies

4 The maintenance of standards of county society work

5 The adjustment of the relation of county medical societies to lay health organizations and to official departments of health

C To the individual members

1 The semi-monthly Journal

2 The annual Directory

3 Defense in malpractice suits

4 Laws for the benefit of the physicians and the public

5 An annual meeting with its scientific, administrative and social features

6 A study of State-wide medical problems, such as nursing, medical economics, industrial medicine, and health centers

7 The extension of fields of practice to include various phases of preventive medicine, such as periodic health examinations, prenatal advice, and the administration of diphtheria toxin-antitoxin

8 There is also the satisfaction of being an integral part of the organized medical profession of the county, the state, and the nation, of taking part in its activities, and of sharing in the benefits and joys of fellowship with medical brethren

LOOKING BACKWARD

THIS JOURNAL TWENTY YEARS AGO

Medical students a generation ago were regaled with discussions as to whether bacteria were plants or animals, and whether the science of bacteriology belonged to botany or zoology. The most obvious approach to the science of bacteriology was through the mushrooms and molds and yeasts, all of which were within the province of the botanists. But it was not botanists, but chemists and physicians who developed the science of bacteriology.

This Journal for November, 1906, discusses this development and says

"In times long past the doctor of medicine, in the interest of his peculiar therapeutics, was a botanist. Little did botany dream that the doctor would boldly open the front door of her ancient castle and walk away with her fairest flower, which now for a score of years has adorned the gardens of the sons of Sol."

"Bacteriology in twenty-five years has had given to it a vast amount of patient research, claiming the sole attention of more devoted men than have worked at botany in a hundred years. Most of these men are unknown to the world, but several hundred of them have contributed equally to the development of this

science. Botany had her great lights, some of the greatest men that any science has known. They have been but few, but they were all great men—Aristotle, Pliny, John Ray, Linnaeus and Asa Gray.

"It is interesting to observe that three of the five botanists were physicians, and two of these physicians were the greatest scientists of their respective centuries. But the greatness of these men was not manifested alone in botany, they were naturalists and pioneers in the field of zoology as well. Had they been living at the time of the birth of bacteriology, it is doubtful if it ever would have departed from botany."

"But the parting came. Bacteriology has grown towards humanity, and has become of infinite, practical, every-day usefulness to mankind. Botany is still the aloof, genteel, aesthetic science. For the bacteriologist, the suffering and dying beckon on. For the botanist the flowers in the meadows nod their heads, the pine trees sing softly their lullabies, and the breezes of summer bear upon their wings the odor of the wayside vines."

WHO PRACTICES MEDICINE?

"Why did you give up the practice of medicine?" is a question that is often asked of physicians who take full-time salaried positions with insurance companies, departments of health, medical journals, social associations, and other organizations which require the services of physicians

Are these physicians practising medicine?

Must they register under the revised practice of medicine act?

These questions have presented themselves for two reasons

1 A common opinion among family physicians seems to be that the salaried doctors have separated themselves from their fellows whose income depends on private practice

2 The Regents have received requests from salaried physicians asking whether or not they must register These requests are made in good faith, for in many instances physicians from other states are employed before they have had time to pass the examinations and secure licenses in New York If one salaried man of a group is excused from registering, then all the others in the group would be under a similar ruling

The legal definition of who should register under the practice of medicine act has not come up for decision It is to be hoped that the question never will be raised, but that every physician will register who does anything for which the degree of doctor of medicine is necessary

Physicians in private practice are urged to take an interest in those subjects in which the salaried doctors are specialists This means the practice of civic medicine and public health among the families of their patients, and also doing their part in the administrative work of

their county medical societies From this it is only a step to assuming a full-time administrative or scientific position with a department of health, or other organization that employs physicians The work of a family physician merges into that of a full time public health worker with no clear-cut line of demarcation between them

The success of the salaried physician depends largely on his intimate knowledge of medicine as practised by family doctors The insurance examiner, the health officer, the medical administrator of a lay organization, all must pass upon the work of family doctors at times, and advise them how to do it They practice medicine when they tell a family doctor what to do It would be to the benefit of all concerned if the medical administrators would go with the family doctors and do some of the work which they require of the family doctors

A physician holding a medical administrative position was recently on the witness stand and was asked if he still practiced medicine, and he maintained that he did, although he no longer examined private patients, or did surgical operations It would be well if every medical administrative physician should assert his claim that he is practicing a specialty in medicine, and should voluntarily register with the Regents under the Practice of Medicine Act The county medical societies have always welcomed these physicians as members, and have accorded them the same privileges and honors that are bestowed upon doctors in private practice It is assumed that every member of a county medical society practices medicine

WHAT DOES THE STATE MEDICAL SOCIETY DO FOR ME?

It is rather difficult to frame a satisfactory answer to the question that has often been asked privately at the District Branch meetings and other assemblies, "What does the Medical Society of the State of New York do for me?" Not that an answer is difficult to find, on the contrary, the answer involves so many items and ramifications that some important ones are likely to be overlooked The tangible immediate benefits may be quickly stated The intangible, inspirational effects are evaluated with greater difficulty

Then, too, there is the personal equation of the members,—whether or not they themselves put a value on what they receive The

benefits may be presented to them, but are they put to use? An excellent scientific article, for example, is of no use to a physician if it is not read To understand and appreciate what the State Medical Society does for its members, one must be interested in it and also in his county medical society

A further point to be considered is the relation of the State Society to the county societies Historically and practically, the county medical societies come first The members of the State Society are those physicians who are elected to membership by the several county societies The governing body of the State Society consists of representatives chosen by the county societies In the ultimate analysis,

nours later there was a chill followed by high fever, vomiting, delirium, and cyanosis and death occurred at 5 o'clock next morning. The diagnosis was foudroyant sepsis due to the staphylococcus. The hospital on hearing of this accident had the rest of the serum tested. Of three phials one was found sterile, one contained only the proteus, and the third contained the staphylococcus. The original motive of the doctor in immunizing this child was its unusual delicacy, for in addition to the exudative diathesis and nervousness there was much tuberculosis in the family. The hospital presumably supplied the serum free and without any guarantee of its sterility. The practitioner assumed that there had been bacteriological control and hence felt no responsibility to stop for tests. Attempts to fix responsibility appear to leave the onus on the government, local or central, because of the lack of a suitable control by the sanitary authorities. Most of the disadvantages and accidents of serum therapy are due to this lack of a central regulating authority which should supervise sera from the first step in manufacture up to the moment of injection.

Hemorrhagic or Vacuum Treatment of Boils
—This treatment has been used by Düker of the St. Norbert Hospital, Berlin, for the past two years. It must not be confused with the treatment of Bier—the suction-stasis produced by the Bier cups—for the vacuum produced by the author's treatment (known familiarly by the name of Kuhn, who first made it public in 1925) is much higher. The suction by the Bier treatment may be spoken of as slight—tenths of an atmosphere only—while in the Kuhn treatment it may go as high as half an atmosphere or more. In place of a mere stasis the effect is actual hemorrhage both within and around the furuncle. Moreover the vacuum is prolonged for a half hour to an hour. It amounts in a way to a form of autohemotherapy in which the patient's own blood is forced into the affected tissues. The apparatus consists of vacuum cups of different sizes and shapes, vacuum tubes of rubber with thick wall and narrow lumen, and a large syringe to produce aspiration. The author mentions no suction manometer in the clinical apparatus but has used one in his experiments and found that the suction produced reached 500 to 600 mm of mercury. To make the apparatus hermetically tight Düker caulks it, so to speak, with cotton and some thick tenacious substance with adhesive strips over all, this is seldom necessary except in certain localities like the nose, where coaptation of the rim of the cup is difficult. One early act of suction usually suffices. Evidently this treatment can promise superior results only in the first stages of fur-

uncles. The immediate result is loss of the tension and pain. The lesion is now simply left to itself and if not aborted the pus may easily be evacuated. Boils treated in later stages require a number of daily sessions.—*Deutsche medizinische Wochenschrift*, July 9, 1926.

The Antiquity of Syphilis—Professor H. E. Sigerist of the Institute for Medical History at Leipzig University has read critically all of the new material on this subject for the past two years and finds but two papers of real value. One is by the Japanese professor Dohi, whose writings have recently been mentioned in this JOURNAL, while the other is from the pen of Dr. Hildebrand of Duisburg. The former inclines to the American origin and holds that Vasco di Gama, the Portuguese circumnavigator, must have carried the new malady from the Iberian peninsula to the East Indian archipelago, whence it eventually found its way to China and Japan. The latent period was 1498 to 1505, the latter being about the year of the earliest outbreak at Canton. This is of course pure hypothesis for the earliest direct contact between the Europeans and the Sino-Japanese did not take place until many years after 1505, so that we have to assume that the disease traveled from port to port among the Asiatics after their first contacts with the Europeans. No evidence is adduced to show the existence of syphilis in Ceylon, the Malayan peninsula, or the Sunda Isles during this latent period or in the years which followed. Dr. Hildebrand inclines to the pre-Columbian European origin and quotes a number of new texts in justification, comprising Odo of Cluni (879-942 A.D.), Sextus Amarius in the XI century, Guillaume de Blois in the XII century, and St. Hildegard, also in the XII century. Perhaps the most convincing passage is by the latter, when he states in substance that "certain men who are addicted to venery fall into a general sickness in which the skin and flesh undergo an ulcerous decay and under the crusts which cover the broad ulcers the red flesh is seen." Professor Sigerist states that both Dohi and Hildebrand rest their cases on hypothesis although he himself is inclined to oppose the American origin. That which spread over Europe in 1495 was not a new disease but there was new knowledge of a disease as yet only imperfectly recognized.—*Deutsche medizinische Wochenschrift*, June 18, 1926.

Rat-Bite Virus in the Treatment of General Paralysis—In a preliminary report, H. C. Solomon, A. Berk, M. Theiler and C. L. Clay (*Archives of Internal Medicine*, Sept. 15, 1926, xxxviii, 3) describe their experiences in twelve cases of general paralysis in which the patients

MEDICAL PROGRESS

Sepsis—Professor Kaiserling opened a symposium on the pathology and therapy of sepsis at a session of the Verein für wissenschaftliche Heilkunde last April, in which he discussed the general nature of the process. The word itself is of course a misnomer for it meant originally putrefaction and in a more modern sense the action of putrefactive organisms on tissue already dead. That which we call sepsis involves the action of disease germs on living tissues. Usually but not invariably the process involves pus formation so that pyogenic organisms and especially staphylococci and streptococci are chiefly active. Sepsis must be distinguished from bacteremia and toxemia and for the sake of having a working definition we may visualize sepsis as the reaction of the organism to the introduction of pyogenic microorganisms into the circulation. According to the degree of reaction we have hyperacute, acute, slow, and chronic sepsis. We may also in place of the degree of the reaction speak of degrees of virulence of the organisms. In malignant sepsis we may imagine a high degree of virulence in conjunction with a patient of low resisting power. In the highest type the only lesion apparent when the patient is fatally overcome—perhaps on the first or second day—may be a little lymphangitis at the site of the inoculation. If the virulence is somewhat less and the patient lives four or five days, we may see extensive local mischief—necrosis, phlegmon, gas phlegmon, etc., while the blood and tissues in general show marked alterations, including hemolysis, high temperature, unusual warmth of the cadaver, cloudy swelling of the viscera, ecchymoses, etc. There is a well known danger to him who makes the autopsy in these cases. In different degrees of sepsis the endocardium seems equally menaced and we see malignant or ulcerous forms in acute, and vegetative forms in slow sepsis. As a rule the arteries escape this process but in rare cases we see a corresponding form of endarteritis.—*Deutsche medizinische Wochenschrift*, July 16, 1926

Gas Sepsis with Methemoglobinuria from a Slight Injury to the Finger—Paul Eichler reports a unique case of rapidly fatal blood poisoning as follows. A powerful young man while working with a circular saw in the local pencil factory cut the pulp of his finger end and received a first aid dressing in which some unknown oil figured. In 20 hours he showed evidence of infection and in two days and a half more was dead. In accordance with severest

sepsis constitutional symptoms developed first—lividity of the face and hands, collapse, vomiting, prostration, somnolence, pains in the frontal region and upper abdomen, low blood pressure, methemoglobinuria, staining of the skin. Blood cultures remained negative throughout. The local wound gaped but showed only slight inflammatory reaction. Spectroscopic tests of the blood showed the presence of methemoglobin. The red cells were much reduced in numbers from the intense hemolysis. A considerable leucocytosis had no significance as it was evidently only relative. Autopsy showed an extensive discoloration of most of the organs from blood pigment. In visualizing the case it was necessary to exclude poisoning with such substances as arsenic, nitrites, and acetanilid and this was readily done. Bacteriological tests of the scanty secretion of the wound showed a mixed infection comprising Fraenkel's gas bacillus which is known to cause methemoglobinemia, and is the only microorganism, aside from the malaria plasmodium, which ever manifests this property. The negative blood tests may therefore be disregarded and Fraenkel himself states that this is to be expected at times. The Fraenkel bacillus appears in the blood in serial crops and hence may be missed. The organism was very virulent to animals. Clinically this case belongs to a group in which the blood change may be a hematoxygenous jaundice, a hemoglobinemia, or a methemoglobinemia. In all such sepsis the tissues including the skin show a discoloration resulting from the hemolysis.—*Muenchener medizinische Wochenschrift*, July 2, 1926

Septic Serum Death—Professor A. Schlossmann of the pediatric clinic at Düsseldorf devotes a long article in the *Deutsche medizinische Wochenschrift*, July 23, 1926, to the effort to fix the responsibility for a serum death and to prevent such accidents in the future. The death occurred in Chemnitz last April and the details have long been public property so that there is no occasion to hold back any of the data. A pediatricist of Chemnitz was summoned to a case of measles and wished to immunize a three year old boy. The request to the local hospital went in by telephone and as there was serum already on hand the doctor sent his chauffeur for it. The bottle was properly sealed and the serum, although cloudy, appeared to be otherwise intact. The doctor used all antiseptic precautions in making his intramuscular injection into the buttocks. Five to six

the report to be on the road to recovery In a discussion of the paper Hieronymi announced that in farcy the infection should start from the intestines, nearly all the ordinary early lesions of the disease being metastases, including those of the nasal fossæ and skin It should be possible to diagnose farcy by a study of the histological structure of the nodules

Nature of Measles—Professor Max Flesch, who many years ago collaborated with Fehleisen when he discovered the bacterium of erysipelas, recalls that his former associate was unable to find any sign of germ life so long as he took his specimens from the reactive zone and that he discovered his *Streptococcus erysipelatis* only when he went into the sound outlying skin before reactive phenomena had developed Something of the same sort, the writer suggests, may be true of the causal organism of measles, or this may not be in the efflorescence at all and may be found only in the blood Recently a child of the author's was exposed to measles and the father proceeded to have the blood tested daily under the supervision of the Frankfurt Institute for Experimental Pathology Nothing was found until the seventh day of the period of incubation when a peculiar short bacillus was recognized which later increased in numbers On the twelfth day the measles eruption appeared Here is a possible clue to the cause of the disease In this connection he points out that those who communicate diseases like smallpox and whooping cough often seem themselves to be well or at least with only simple ordinary ailments, as when a child with a slight cough transmits undoubted whooping cough The author does not refer to carriers in the ordinary sense but to individuals in whom the nature of the infection is masked Here again is the example of virulent germs in sound tissues or apparently sound individuals In connection with his find of a microorganism in the blood of measles incubation he advocates the use of the measles convalescent serum by the sixth day after exposure or as late as the tenth, before there are many of the organisms in the blood—*Muenchener medizinische Wochenschrift*, September 3, 1926

The Dick Toxin and Scarlet Fever Streptococcus—R. Bieling, the chief of a large serum institute, refers to the positive advantages of the Dick toxin in fixing susceptibility and of the antitoxin in neutralizing it in the laboratory and clinic, but adds that there are peculiarities of these substances which argue against true specificity of action We can obtain this toxin by culture, and we obtain the skin reaction in the susceptible but not in the convalescent, though we obtain positive results up to the time of

convalescence We can mix the toxin with immune blood and thereby neutralize the former But strange to state we cannot get such results in animals (sheep, pig) Clinical convalescents do not run parallel with toxin-insensitives and there is the hint that other factors exist in securing immunity aside from antitoxin-formation Very puzzling is the fact that the Dick toxin, complete in all its behaviors, can be produced by cultivating other pathogenic streptococci, such as those which cause erysipelas, meningitis, lipoid nephrosis, and puerperal fever Moreover there are probably streptococci in scarlatinal patients which are not the same as the scarlatina streptococcus but which may be able to produce the Dick toxin Any of these non-specific streptococci will form the latter, will give the Dick skin reaction, and may be neutralized by convalescent serum Moreover there is evidence that true scarlatinal streptococci may fail to produce the typical Dick toxin So long as matters stand thus, the author thinks it may be injudicious to push Dick tests and Dick immunization on too colossal a scale among the general populace, although he admits that rather inconsistently that we should certainly make use of them in actual epidemics and after exposure, and treat all cases of true toxic scarlatina with the antitoxin—*Muenchener medizinische Wochenschrift*, September 3, 1926

Lipoid Nephrosis in Childhood—Professor A. Eckstein discusses the incidence of lipoid nephrosis in childhood in a somewhat sceptical vein, for three cases reported by him in which this diagnosis would seem to have been justifiable turned out to be something different. In true lipoid nephrosis as it occurs in adults the symptoms are well marked—noticeable disturbance in the economy of water and salts, edema subject to notable fluctuations, albuminuria, often in high values, more or less of formed elements in the sediment, and most important of all the double refractive lipoid granules or droplets which must be present to establish the diagnosis The first of Eckstein's cases ended in recovery so that the exact diagnosis was in doubt, but the author did not feel justified in calling it anything more than a temporary lipoiduria The second case was regarded during life as one of a typical lipoid nephrosis, but at the autopsy the kidneys were found to be the seat of a pneumococcal infection and the case was set down as a pneumococcal nephrosis with lipoiduria The third patient showed tabes mesenterica and amyloidosis which was especially marked in the kidneys The diagnosis was amyloid kidneys with lipuria It is evident that even with the typical clinical picture of lipoid nephrosis the diagnosis may be wrong—*Klinische Wochenschrift*, September 17, 1926

were inoculated with *Spirochaeta morsumuris*, the etiological agent of sodoku, in an attempt to improve upon the malarial method of Jauregg. Sodoku, or a rat-bite fever, is a disease fairly common in Japan, and has occasionally been recognized in the United States as well as in most other countries of the world. The infection is produced by the bite of a rat or certain other animals infected with this spirochete. The disease produces a number of symptoms suggestive of syphilis (a sore somewhat like a chancre, a regional lymphangitis and a generalization of the spirochetosis). After from five to twelve days fever occurs and skin lesions appear quite similar to those of the secondary period of syphilis. Sodoku can be transferred to man by either intradermal or intravenous inoculation of the blood of an infected animal. The intravenous method seems preferable because it avoids the formation of the primary lesion and lymphangitis. The usual dose is 1 c c intradermally or 0.1 c c intravenously. The artificially produced disease is similar in its clinical manifestations to the naturally acquired disease, producing repeated paroxysms of fever of from 102° to 105°F, and is readily controlled by asphenamine in 0.3 gram doses. Sufficient clinical and serological improvement has been noted in some of the patients treated by sodoku to suggest that its therapeutic value is equal to that of malaria. In addition, it has the practical advantage that it can be maintained in laboratory animals, and is thus always available for use, which obviates the necessity of transmitting human blood and of having on hand a case of human malaria. Furthermore, the disease is less debilitating to the patient than malaria, and it can be given to patients who are more or less immune to malaria. It may also be used together with malarial therapy.

Thirty Years Experience with the Thyroid Treatment of Obesity—Carl von Noorden refers to the simultaneous application of thyroid tablets in the treatment of obesity by himself, Yorke-Davies, and Wendelstatt and Leichtenstern about 1895. The new remedy was in such demand that the manufacturers could hardly meet it, and presently there was a reaction against the utility of the treatment and its dangers. Most of the profession dropped thyroid incontinently for this purpose, the author, however, having been an exception. To orient ourselves rapidly as to the value of this treatment, a distinction should first be made between obesity from overeating and physical torpor and the same symptom when due to an endogenous suboxidation. In the former, thyroid can serve no useful purpose, while in the latter it may be indicated, although not in-

variably. It may be possible to reduce the patient without recourse to it, especially in mild cases. Moreover in some of these patients there is evidence of hypothyroidism and in these the drug is specifically indicated. Use of thyroid substance does not mean that other resources are to be neglected. But outside of any special indications the remedy must be given perseveringly, for loss of weight even in a slight degree may not appear before a fortnight. Tolerance for the treatment may come about from too large doses and also from keeping up the treatment over too long a period. One should never go above a maximum of say the equivalent of less than a drachm of fresh sheep thyroid, which combines specifically 12 mg of iodine, and the treatment should be often interrupted to prevent the development of tolerance. It is best to think of a course of treatment of six months to a year with gradual, steady loss of weight although patients often rebel against this protracted treatment. We may isolate a third form of obesity which represents a hybrid between forms 1 and 2 and in this type the hormonal treatment must be added to ordinary reduction methods.—*Klinische Wochenschrift*, July 2, 1926.

A Case of Farcy—Blohmke reported the following case at a meeting of the Verein für wissenschaftliche Heilkunde (*Deutsche medizinische Wochenschrift*, July 2, 1926). For several weeks a man had complained of dysphagia, with fever, chills, and prostration. On examination superficial ulceration was seen on the tonsils and adjoining soft palate with a certain amount of cervical lymph-node swelling. The margins were livid and sharply marked off from the surrounding tissue. The diagnosis lay between syphilis and tuberculosis, but a biopsy showed non-specific chronic inflammation. The Wassermann test was repeatedly negative after salvarsan provocation. An abscess now formed behind the left tonsil and was incised. A suspicion of farcy being aroused, the pus was tested for the *Bacillus mallei*, but remained persistently negative. The appearance of a nodule in the muscles of one of the extremities awakened again the suspicion of farcy which was still further strengthened by the fact that some months before two horses of the patient had to be killed for glanders. A mallein allergic test was positive and serological tests were also conclusive—agglutination and complement deviation. Inoculation of the abdominal cavity of a guinea pig caused the characteristic lesions of the testes. The throat lesions improved as if from the treatment but severe manifestations appeared in the nasal fossæ with secondary suppuration of the right lacrimal sac. The patient, after an observation period of six months, appeared at the time of

the community, there, if nowhere else on earth, he will be judged simply as a man. Twelve pairs of eyes are riveted upon him from the jury box, the judge at his right is watching him, and both lawyers are observant of his every word, gesture and expression. Times without number the story of a witness is appraised and judged as much by his appearance and his conduct on the witness stand as by anything he says. Every word he utters will be taken down and investigated and every movement of his head and glance of his eye will be scrutinizingly observed. It is indeed a test.

Oftentimes a client has said to counsel before his case has come on for trial, "What shall I do? How shall I act when I am on the stand?" Some of the answers made to this query may not be without interest.

FIRST *"Tell the truth"* Remember that before you testify you will take an oath "to tell the truth, the whole truth and nothing but the truth." This is a moral maxim, but it is far more than that, it is a practical one. The Creator of Mankind seems to have imparted to every human mind some strange and infallible power to discern when a person is telling the truth and when he is not. If the truth, the whole truth and nothing but the truth is told, the likelihood that a witness of ordinary intelligence will be confused in telling it is immeasurably decreased. When an honest man is trying to narrate honestly what he actually said, saw, heard or did, he will not be engaged in the parallel attempt of trying to make one word reconcile itself with another or become confused in an effort to make his story plausible. Instead he will be devoting his entire mind to recalling what the facts were and to the expression of them in plain and simple words. There is a look about a man who tells the truth which is unmistakable. This is equally true of a witness who is lying. These things a jury of twelve men, by some strange second sight, seem able to divine. Tell the truth and you will not become confused in your testimony! This does not mean that it is unimportant before the trial begins to spend every reasonable effort in recalling the facts and in refreshing the recollection as to names, dates and circumstances from such records as the witness may possess. This must all be done before the trial. When it is done, if the witness tells the truth he not fear but that he will be believed. The witness who has fabricated his story, however deftly—in the hands of a shrewd cross-examiner will be detected and exposed and, when detected and exposed, the judge and the jury will lose every vestige of confidence and respect for him, and he

should not be disappointed if that occurs which, under those circumstances, should occur—an adverse judgment.

SECOND *"There is no magic about testifying"*—There are no abstruse or hidden rules which govern it. A courtroom is a practical place where practical men are engaged in the serious work of endeavoring to administer justice. Do not try to assume a pose or studied mien, do not think about anything except giving, in a straightforward way, true answers to the questions which the judge allows.

THIRD *"Be courteous"*—This applies to the judge, the jurors and the adverse counsel. No one ever loses by courtesy. Do not try to be facetious or smart. No matter how absurd a question may appear, consider it seriously and give a truthful and intelligent answer. The folly of a question will be more exposed by the calm intelligence of the answer than by any smile or sneer or other manifestation of the scorn of the witness for the ignorance or shortcomings of the questioner.

FOURTH *"Do not be afraid"*—The honest man who is coming into court to tell the truth has nothing whatever to fear. As a rule he will be dealt with courteously, and if he is not dealt with courteously by the adverse counsel, the judge will come to his protection and he will enlist the sympathy of the jury. Look the examiner in the eye and look into the eyes of as many of the jurors as you can. If the judge asks a question, turn and look him squarely in the eye and give your answer. Remember that it is not only your story, but you, that is being judged. No one loves a coward. You have nothing to fear. Sit there with head erect and be yourself.

FIFTH *"Do not seek to impress the judge the jury or the adverse counsel with the possession of superior wisdom"*—Nothing is more impressive than modesty. If you are an outstanding character or are the possessor of extraordinary attainments, this fact will soon enough reveal itself. Minimize rather than exaggerate your qualifications and capacity.

SIXTH *"Be attentive to the questions"*—Listen to the questions carefully. Make sure that you understand them. Do not answer them until you do understand them. You cannot understand them unless you listen to them. After you understand them, answer them in the most straightforward and truthful manner possible.

SEVENTH *"Do not volunteer"*—The trial of a case does not consist of the speeches of the witnesses, but of their answers to specific questions. In the hands of competent counsel the facts will be elicited by questions. You are not called upon to make a speech, your only duty is to give answers to the questions which are put to you.

LEGAL

By LLOYD PAUL STRYKER, Esq
Counsel, Medical Society of the State of New York

THE ART OF GIVING TESTIMONY

Many interesting and important principles governing the administration of justice have found but slight reflection in the books. Until Francis I. Wellman wrote his brilliant work on the "Art of Cross-Examination," the rules governing this most invaluable weapon for the ascertainment of truth had not been so illuminatingly set down. Other subjects still await a full and clarifying presentation.

From the trial of hundreds of cases the writer has reached some conclusions in regard to that which might be called "The Art of Giving Testimony." No matter how well a case may be prepared for trial or how skillfully the trial may be conducted by the lawyer, good results sometimes are not achieved because of the failure of a witness to apprehend the true nature of what he is called upon to do.

To the writer there is no more interesting study than the conduct of a lawsuit. There is nothing which brings to bear so many and so varying factors, there is nothing which provides a more useful clinic for a searching study of human psychology and personality. A trial is more than a trial, it is a human drama. A story is unfolded with all of the high lights—fear, pathos, sympathy, anger, indignation and other human traits and emotions—the true materials for the dramatist.

The highest tribute to individualism and to the conscience and intelligence of the ordinary man was paid when the founders of our Anglo-Saxon jurisprudence centuries ago in England came to the conclusion that twelve citizens selected from the varying walks of life were qualified to be the judges of the facts in all court contests between man and man and between the State and its citizens.

The writer for more than sixteen years has been constantly appearing before courts and juries. The longer his experience the more profound his admiration for the jury system. Criticisms of this system of administering justice are not infrequent, but it is the writer's belief that they are usually voiced by those who have but slight experience with juries. When these criticisms are expressed the words of Jeremiah Black, who was Attorney General of the United States in the late fifties, are called to mind. Before the Supreme Court of the United States in one of the most celebrated cases ever argued there, he declared: "The framers of our Constitution could act only in the ex-

perience of that country whose history they knew most about, and there they saw the ferocity of Jeffreys and Scroggs, the timidity of Guilford, and the venality of such men as Saunders and Wright. It seems necessary, therefore, not only to make the judiciary as perfect as possible, but to give the citizens yet another shield against his government. To that end they could think of no better provision than a public trial before an impartial jury.

"We do not assert that the jury trial is an infallible mode of ascertaining the truth. Like everything human, it has its imperfections. We only say that it is the best protection for innocence and the surest mode of punishing guilt that has yet been discovered. It has borne the test of a longer experience, and borne it better than any other legal institution that ever existed among men. England owes more of her freedom, her grandeur, and her prosperity to that, than to all other causes put together. It has had the approbation not only of those who lived under it, but of great thinkers who looked at it calmly from a distance, and judged it impartially. Montesquieu and De Tocqueville speak of it with an admiration as rapturous as Coke and Blackstone.

"Those colonists of this country who came from the British Islands brought this institution with them, and they regarded it as the most precious part of their inheritance. The immigrants from other places where trials by jury did not exist became equally attached to it as soon as they understood what it was. There was no subject upon which all the inhabitants of the country were so perfectly unanimous as they were in their determination to maintain this great right unimpaired.

"If the men who fought out our Revolutionary contest, when they came to frame a government for themselves and for their posterity, had failed to insert a provision making the trial by jury perpetual and universal, they would have proved themselves recreant to the principles of that liberty of which they professed to be the special champions. But they were guilty of no such thing."

When a citizen is called upon to take the witness stand, he must go there alone. When he sits down to answer questions under oath, he must meet the ordeal by himself. Whatever may be his rank or station in life, or the financial or professional position which he holds in

MEETINGS

THE EIGHTH DISTRICT BRANCH

The Annual Meeting of the Eighth District Branch of the Medical Society of the State of New York was held on October 13, in the Buffalo City Hospital, and was opened at 10 30 A M by the President, Dr George W Cottis, of Jamestown

The morning was devoted to topics relating to civic medicine, especially those which are conducted by County Medical Societies A luncheon was served at noon through the courtesy of the Medical Society of the County of Erie An afternoon session was given over to scientific medicine. A subscription dinner was held in the evening in the Hotel Statler, and an evening session was held in conjunction with the Buffalo Academy of Medicine, when Dr John Phillips of Cleveland, Ohio, spoke on "Subacute Bacterial Endocarditis"

President Cottis opened the meeting with his presidential address, in which he outlined a plan for promoting the usefulness of the District Branches He spoke as follows

"The District Branch Medical Societies are supposed to form a connecting link between the component County Societies and State Society It is probable that at one time this was an important and necessary function During the past few years there has arisen a doubt as to whether this Branch Society in its present form is meeting its full usefulness For four years preceding my election, the Eighth District Branch Medical Society was fortunate enough to have for its President Dr Harry Trick, whose enthusiasm and hard work have been appreciated by every member of the Society In spite of the advantage of such leadership, the meetings have never been well attended, and the results have been small in proportion to the time and labor freely expended by our officers

"Last Spring the Council of the State Society authorized the holding of meetings of the Executive Committees of the Branch Societies at dinner conferences, the cost of the dinners being borne by the State Society Our meeting was held in Buffalo and we had a surprisingly good attendance Furthermore, it was discovered that your officers had so many matters to discuss that one evening was not found to be sufficient

"I would suggest for your consideration a proposal that the District Branch Society should function largely through its Executive Committee The Executive Committee is composed of the officers of the District Branch Society, and the Presidents and the Secretaries of the component So-

cieties These men might meet twice a year and function very much as the House of Delegates does for the State Society The traveling expenses of the County officers might be paid by the County Societies, and those of the District officers by the State Society

"At these meetings, the County Societies could present their problems and proposals for discussion, and these discussions would surely be more fruitful than those which we now have at our general meetings More and more each year we must give consideration to the questions of public health, social medicine, compulsory health insurance, and the other movements which result from the civic tendencies of our time. These are matters for intensive study and discussion, and can be handled more effectively by a small group of officers than by a haphazard collection of doctors at a general meeting in which their interest is divided between a series of addresses in the morning and a scientific program in the afternoon"

Dr Joseph S Lawrence, Executive Officer of the Medical Society of the State of New York, addressed the meeting on the need of more meetings or conferences of the District Branches in order to establish a greater liaison between the County Societies and the central State Society While it is impossible to have an intimate discussion of local problems when the representatives of sixty counties are assembled, as in the State Society meeting, it is possible in an assembly from seven or eight counties, as in the District Branch meetings

Dr Robert E DeCeU, President of the Erie County Medical Society, discussed the points raised by Drs Cottis and Lawrence. He spoke of the need of keeping the members informed regarding the activities of the County Society, and Erie County was meeting the problem by publishing a Monthly Bulletin But the Bulletin costs considerable money, and the funds of the County Society are low Dr DeCeU suggested that the District Branch might publish a bulletin for the benefit of all the County Societies of the District, and that the cost might be met by advertisements

Dr DeCeU brought up the point that the members of the Erie County Medical Society pay to the State Society more money than to their local Society, and he asked for a statement of what the State Society is doing for the members in Erie County

Dr Dougherty, Secretary of the Medical Society of the State of New York, in answer to Dr

EIGHTH *"Do not attempt to be an advocate"*—Leave the advocacy to your counsel. Your duty is to give the court the facts, not to argue about them or to draw conclusions from them. This presumably will be adequately performed by the counsel to whose hands your case has been entrusted.

NINTH *"Do not lose your temper"*—Sometimes questions which seem to have a most insulting innuendo are propounded. Ignore the insult, intentional or unintentional, in the question, and conserve your mental powers for answering it. A calm and dispassionate answer to such a question will win you friends among the jury which no angry or intemperate retort could ever bring.

TENTH *"Be natural"*—Do not under-dress or over-dress for the occasion. Be yourself as you are in your own life. You are neither dressing for nor acting a part. You are there as a man to let the judge and jury see, observe and judge you as you are. Affect no mannerisms of speech or dress.

ELEVENTH *"Keep your voice up"*—Your testimony will be of no consequence unless it is heard. In our courtrooms, especially in the larger cities, there is often much noise and confusion. Many times the passing trucks and heavy vehicles in the street will cause a rumble that makes it difficult to hear the voice within the courtroom. It is always a strain and an annoyance, both to the judge and to the jury, if they are not able clearly to hear every word uttered. It is also a nervous tax upon your counsel if his mind must be frequently deflected by exhortations to the witness to speak so that he can be heard. Moreover, there is a psychological value in talking clearly. A man who whispers or mumbles or hesitates sometimes conveys the impression that he is doing so because he is afraid or because in his heart he knows that he is not testifying truthfully. Do not be afraid to speak the truth, the whole truth and nothing but the truth in a voice that all the jurors, the lawyers and the judge can hear.

TWELFTH *"Be frank"*—Do not hesitate to admit a fact because you think it may hurt you. Usually in every case there are some facts which your counsel might wish were otherwise. The best way to meet them is to be frank about them. Candor and frankness win respect and confidence.

THIRTEENTH *"Remember that there is no mystery about the administration of justice"*—A cause and a witness are judged exactly in the same way in which men and circumstances are appraised in ordinary life. The same rules which guide the credit men, the storekeepers, the bankers and the farmers who may sit upon your jury, in their ordinary vocations, will be employed. They will size you up and judge you in the same way in which your banker does when you go to him seeking for a loan. If you are open, frank, honest, to your banker, he will be convinced that you possess that prime prerequisite of credit—character. In the same way in which your banker judges you, your jurors will judge you also.

FOURTEENTH *"Do not be afraid, because your case may involve technical or scientific facts, that they cannot be understood"*—The most complicated proposition in science is susceptible of being expressed in short and simple English words which men of ordinary intelligence can understand. Even a complicated science may be so illuminated and presented that the ordinary mind can grasp it, at least in its essence. Therefore, do not talk down to the jury. If there is a scientific fact concerning which you are questioned and you are accustomed to the use of long Latin words, without any display of superior learning translate and explain these words into simple terms so that they can be understood. Sometimes polysyllables are nothing more than a disguise for an imperfect knowledge.

Without in the least attempting to be didactic, certainly with no assumption of a perfect mastery of the complicated art of presenting a case to a court or jury, the writer from his own experience feels that the foregoing rules, simple and obvious as they may seem, if fully comprehended and observed, would be the means of winning many a case which otherwise might seem desperate or hopeless.

the Erie County Medical Society The collection of pathological specimens that was shown last year was again on exhibition For a description of the specimens, see this Journal, November 1, 1925, page 1014

Another feature of the exhibit was a series of charts designed to educate the public in the elementary facts of disease. One chart, for example, showed an outline of the nervous system on which was indicated the site of the lesions of poliomyelitis and the place of entrance of the germs The exhibit also contained food specimens showing the composition of various articles of diet and their calories

A third feature of the exhibit was a series of fourteen charts setting forth in a popular way the fundamental basis of the practice of medicine Some of the charts, for example, compared the educational requirements of a doctor with those of a cultist These charts were prepared by Dr E W Koch, Professor of Pharmacology in

the Medical School of the University of Buffalo, and were first shown at the dinner given by the Erie County Medical Society on May 26, 1926, to the members who had been fifty years in practice These charts will be published in an early issue of this Journal

Dr Goodale also showed the members of the District Branch the building which had recently been erected to house a school for crippled children Over one hundred school children are brought to the building daily in busses at city expense. They attend classes in the ordinary school subjects, and are also given manual training in work suitable to their physical defects Doctors examine the children daily and give them the treatments which they need The building has abundant room for carrying on every needed activity, and is the latest development in the rehabilitation of cripples who otherwise would be condemned to a lonesome life isolated from companions

THE FIFTH DISTRICT BRANCH

The Twentieth Annual Meeting of the Fifth District Branch of the Medical Society of the State of New York was held on October 14, 1926, in the Y M C A. Building, at Watertown, with the President, Dr Charles D Post of Syracuse, in the chair

The first number on the program was "Some Medical Problems in School Health Inspection," and was given by Dr Mace of the State Department of Education The doctor enumerated four defects which were noted by the inspectors

- 1 The substitution of a nurse for the doctor in making examinations

- 2 Commercialism, such as prescribing glasses when none were needed

- 3 A deficiency of educational publicity regarding the examinations and the correction of the defects

- 4 "Steering" patients to certain doctors—a criticism of lay agencies

Dr F W Sears, District State Health Officer, in discussing the paper, told of a successful experiment in getting better examinations in rural schools, consisting of the following steps

- 1 A letter to the school trustees explaining the plan and offering cooperation

- 2 A public health nurse visits the school in order to weigh and measure the children, and to test their sight and hearing She would use apparatus supplied by some health center or nursing association.

- 3 On an appointed day the nurse and the doctor would go to the school house, and the doctor would examine the children behind a screen, while the nurse made the records No difficulty was found in stripping the children to the waist for the examination

- 4 The nurse made subsequent visits in order to instruct the teachers and parents in the follow-up work

The second number on the program was "Diphtheria Eradication" by Dr F G Metzger, of Carthage He described the work in Carthage and the difficulties encountered The result of giving toxin-antitoxin to the school children was that scarcely a case of diphtheria now develops in the village

One difficulty mentioned by Dr Metzger was that at first some adults had sore arms and a fever following the toxin-antitoxin injections, but none were seen during the last two years since the use of the newer mixture containing only one-quarter as much toxin as formerly

Dr John M Swan of Rochester, Chairman of the New York State Committee for the Control of Cancer, gave a clear description of the aims of the Society He emphasized the ten points of the statement regarding cancer which was issued by the International Cancer Symposium recently held in Lake Mohawk, and which are described on page 878 of the October 15 issue of this Journal Dr Swan also described the cancer clinic which was begun in Rochester in 1924, and said that only about 18 per cent of the cases coming to the clinic had cancer This fact shows that the education of the people regarding the early signs of cancer was having its effect.

Dr W Richard Ohler, of Boston, gave a paper on "The Present Status of Thyroid Therapy" He began by describing the use of basal metabolism tests in the diagnosis of thyroid defects He then enumerated the signs of increased activity of the thyroid as follows A

DeCeU's question, outlined some of the major activities of the State Medical Society. He divided the problems of the State Society into three classes: 1, scientific, 2, preventive medicine, and 3, policies of administration.

The scientific activities of the State Medical Society are the oldest and best known of all its forms of work. The most recent form of scientific activity is that of graduate education, whose benefits are open to any County Society which will use them.

Active participation in the concrete applications of preventive medicine is also one of the newer forms of work of the State Society. This activity, like that of graduate education, is not conducted directly by the State Society, but is done through the County Societies interested in the work.

Regarding policies of administration, there are some things which the State Society itself handles, and others in which the State Society acts as advisory to the County Societies. Examples of activities which are peculiar to the State Society are legislative matters and malpractice defense.

The advisory and inspirational work of the State Society depends largely on the intimate contacts of the committees and officials of the State Society with those of the County Societies and the local members. Concrete forms of these contacts are afforded by the Journal of the State Society and by the field work of the Executive Officer.

How much benefit a County Medical Society or its members get out of the State Society will depend largely on the desire and receptivity of the local organizations and members. The State Society discourages the passive acceptance of favors, but it helps any County Society or member in the active development of all forms of the practice of medicine.

Dr. Dougherty developed the value of intimate sociability as a promoter of harmonious activity for the good of the medical profession. The trinity of activities of the medical societies of the State, the District Branches, and the Counties consists of, 1, the scientific, 2, the civic, and 3, the social. The social activities are not ends in themselves, but are essential in securing harmonious action along scientific and civic lines.

Dr. George M. Fisher, President of the Medical Society of the State of New York, gave an address on the broad lines of work done by the State Medical Society in the past, especially its leadership in the promotion of laws relating to the practice of medicine, the adoption of a pharmacopoeia, and the formation of the American Medical Association. He also described the broad lines of activity that are now carried on by the State Society, and its still broader plans for the future. The present is a period of research and experimenting along such lines as graduate education, periodic health examination, diphtheria prevention, and the control of quackery.

The State Society had builded on sure foundations, and future progress will depend largely on the active response of the medical profession to the ideals set forth by progressive leaders in the State Society, the District Branches, and the County Societies—all of whom are actively developing plans by which the physicians of New York State may meet their full obligations as advisors of the people in all matters relating to sickness and health.

The anti-diphtheria campaign in Erie County was described by Dr. Joseph O'Gorman of Buffalo. He said that the work was being promoted by five principal means:

- 1 The County Bulletin describing the plans was sent to every doctor in the County.

- 2 An ornamental display card for the physicians' office was sent to every doctor. This card called the attention of patients to the benefits of toxin-antitoxin, and stated that the doctor was prepared to give the immunizations.

- 3, A monthly check-up of the number of packages of toxin-antitoxin given out by the Department of Health, and of the number of reports of doses given in clinics and by private doctors. The pediatricians were especially active in giving the immunizations.

- 4 Publicity in the newspapers.

- 5 Publicity in the moving picture theatres.

In the discussion, Dr. Lawrence said that Erie County was responding to a public demand aroused by the State Department of Health and lay organizations.

Dr. Fisher called attention to the five-year program with the slogan "No diphtheria by 1930." He said that if the doctors did not give immunizations, the State Department of Health would do so. He appealed to the doctors to take advantage of the opportunity that was offered to them.

Dr. Dougherty told of the attitude of doctors toward diphtheria antitoxin when it was introduced in 1895. He said that the doctors of New York City usually sent word to the Board of Health when they had cases of diphtheria, and asked that a doctor be sent to give the antitoxin regardless of the social status of the family. Today the doctors were better educated, and were more willing to discharge their civic duties.

The following scientific program was carried out during the afternoon session:

"The Relation of the General Practitioner to the Workmen's Compensation Law," H. P. Hourigan, M.D., Buffalo.

"The Advisability of Pregnancy Complicated with Diabetes," Byron D. Bowen, Buffalo.

"Benign Diseases of the Cervix and their Treatment," James E. King, M.D., Buffalo.

"Surgery of the Spleen," Thew Wright, M.D., Buffalo.

Dr. Goodale, Superintendent of the City Hospital, showed those attending the meeting an exhibit that had been prepared by the Hospital and

- street cleaning department, Philadelphia

Heart, 1924

To describe the forty and more meetings of the Association here would be impossible owing to the limitations of time and space. But some of the leaders kindly consented to give statements of their impressions.

Dr. C. E. A. Wilslow, President of the Association, said:

"The great future problem in public health is the control of the degenerative diseases, such as cancer and the chronic diseases of the heart and kidneys. Their control depends on preventive work. Can this work be left entirely to the individual doctor? Medical organizations are needed to stimulate and help the individual doctor to seek to treat the individual cases, and to educate the cases to seek early medical treatment.

"The question arises, can prevention be made effective under all conditions as long as the remedy depends on individual pay? The question is settled in Europe by the adoption of a system of State medicine. In this country the remedy is in the hands of the doctors themselves. They have the power to see that practical measures are developed and adopted. The group including the poor and the unwilling must be reached, and if the doctors do not reach them by means of their organizations, either the State or lay organizations will reach them.

"Physicians are beginning to realize their vital interest in the problem, and are earnestly attempting its solution through their organizations—national, state and county."

Dr. Henry F. Vaughan, Past President of the Association, and Health Officer of the City of Detroit, said:

"The public health need of the day is a working liaison between all health practitioners—the family physicians, laboratory workers, health officers, lay workers, and all others engaged in public health work. A concrete suggestion is that the representatives of the American Public Health Association should meet with similar representatives of the American Medical Association, and adopt working standards of cooperation.

"There is need of a closer harmony between

sense of warmth of the skin, flushing and perspiration, heart rapid, nervousness, tremors, increased appetite, loss of weight, exophthalmic symptoms

The signs of decreased thyroid activity were retardation, physical and mental, low blood pressure, cold skin, abnormal sensitiveness to cold, slow pulse, slow speech, decreased appetite, increased weight, edema, pallor, decreased intestinal function

The intensity of the symptoms were in direct proportion to the departure from the normal rate of basal metabolism

Dr Ohler then described therapeutic measures in a clear simple way

Dr George M Fisher, President of the Medical Society of the State of New York, described the activities of the State Medical Society, and what it is doing for the benefit of the medical profession and the public. For the medical profession or the doctors in general, the State Society is doing work along legislative, economic, and educational lines. For the County Societies the State Society is supplying information and inspiration, and for the individual members it is

giving malpractice defense information through the JOURNAL, and the inspiration and satisfaction that comes from close association with other doctors

Dr D S Dougherty, Secretary of the State Society, followed up the lines of thought of Dr Fisher, and emphasized the point that the members would receive benefits in just the proportion that they took an interest in the Society and promoted its work. He suggested the Motto "He who helps is himself helped"

The doctors and their wives were guests of the Jefferson County Medical Society at a noon luncheon

The program of the afternoon session was as follows

"The Importance of the Early Recognition of Urologic Pathology," by Henry G Bugbee, M D, of New York City

Discussion led by Dr Thomas F Lowne, of Syracuse

"Acute Suppurative Pleurisy," by James M Hitzrot, M D, of New York

Discussion led by Dr Hyzer M Jones, of Utica

THE AMERICAN PUBLIC HEALTH ASSOCIATION

The American Public Health Association held a four-day session from October 11 to 14, 1926, in the Hotel Statler, Buffalo. It is composed of all the agencies which are engaged in public health work, especially the official workers in Departments of Health. Lay organizations are also represented, and to a less extent, practising physicians. It includes sanitary engineers and laboratory technicians, and teachers of public health. Its president is Professor C E A Winslow, Dr Ph, who is head of the Department of Health of the Medical School of Yale University.

The registered attendance was about 1,400, which was about 40 per cent more than last year, but a large proportion of the increase was due to the coincident conference of New York State Health Officers, many of whom belong to the American Public Health Association.

The scientific work of the Association is distributed among the nine sections of public health administration, laboratory, vital statistics, public health engineering, industrial hygiene, food and drugs, child hygiene, health education and publicity, and public health nursing, each of which held its own sessions. General sessions were also held. Altogether about 45 separate meetings were listed on the official program, but numberless unlisted committee meetings and conferences were continually going on.

One great accomplishment of the American Public Health Association is the establishment

of standards of procedure. The leading workers in water supplies, for example, have agreed on a standard method for water analysis, and another committee has established standards for milk examinations. A committee is now working on a revision of the quarantine rules for the control of communicable diseases. When the leading experts in any line of public health work agree on a practical method, and the section discusses and adopts it, that method represents a standard which is as nearly official as any such scientific standard can be in the rapidly changing state of science.

Exhibits of material used in public health work were shown on a scale equalling the medical exhibits at the annual meeting of the Medical Society of the State of New York. A striking exhibit prepared by A P H A for sale was a large wall chart entitled "Milestones of Public Health in the United States." It was illustrated with outline drawings which a girl artist, standing on a platform, would color for the buyer at a special price. The milestones on the chart were as follows:

- 1639 Colonial birth and death registration law
- 1647 Act forbidding pollution of Boston Harbor
- 1648 Maritime quarantine in Massachusetts Bay
- 1701 Isolation of smallpox required
- 1750 Benjamin Franklin organized the first

the great amount of money invested in all phases of the work, and the varied professions that are engaged in public health activities. To attend such a conference is an opportunity as well as a pleasure and satisfaction.

The registration of health officers was 360, which was 70 per cent of their registration last year. The reduced attendance may be accounted for partly by the location of the meeting place at the extreme western end of the State, and also by the necessity of missing the intimate sociability of the gatherings in one Saratoga Hotel.

The nurses registered numbered 235, which was 90 per cent of their registration last year.

The example set last year of inviting the President of the Medical Society of the State of New York to take a prominent part in the program was again followed this year. Dr Fisher happily set forth the growing interest which physicians generally, as well as health officers, are taking in public health work, and the increasing cooperation between the State Department of Health and the organizations of physicians, especially the Medical Society of the State of New York.

The State Health Officers' Association under its president, Dr Stanton P. Hull, held its annual meeting and banquet in the Hotel Lafayette, on the evening of October 12, in connection with the association of Public Health nurses under the presidency of Miss Bertha Gibbons. Dr Hull and his associate officers were unanimously re-elected. A feature of the business meeting was the voting of a substantial sum of money to the wives of the Secretary and the Treasurer for

their efficient assistance of their husbands in their clerical work.

The program of the meetings of the Health Officers' Conference was as follows:

Introductory address, Matthias Nicoll, Jr., M.D., Commissioner of Health. This address is printed on page 883 of this JOURNAL.

Address, George M. Fisher, M.D., President of the Medical Society of the State of New York.

"What New York State is doing for Cripples," by Lewis A. Wilson, Director Division of Vocational and Extension Education, State Department of Education.

The Progress of the Toxin-Antitoxin campaign in New York State, by Edward S. Godfrey, Jr., M.D., Director Division of Communicable Diseases, State Department of Health.

Progress of Infant and Maternity Hygiene Work, in New York State, by Elizabeth M. Gardiner, M.D., Director Division of Maternity, Infancy and Child Hygiene, State Department of Health.

Control of Nuisances by Health Officers and Local Boards of Health, by Charles A. Holmquist, Director Division of Sanitation, State Department of Health.

Conferences of groups and special workers were frequently held, and possibly of still more importance were the informal conversations of pairs and groups that were constantly going on in the corridors and meeting rooms.

Altogether the conference was well suited to inspiring the health officers to be better physicians as well as health officials.

THE ASSOCIATED PHYSICIANS OF LONG ISLAND

The last of the three meetings held annually by the Associated Physicians of Long Island was held in the Engineers' Club, Roslyn, Long Island, on the afternoon and evening of Tuesday, October fifth. The afternoon was taken up with a golf tournament at which fifty-four members competed for seven prizes.

A business session was held at 5:30 o'clock at which six new members were elected. A report of the *Long Island Medical Journal*, the organ of the Society, was given by Dr W. H. Ross, Chairman of the Publication Committee, who showed the progress of the *Journal* in reflecting the medical activities of the four county medical societies on the Island.

A supper was served at 6 o'clock at which eighty-eight physicians were present.

A scientific session was held at which Dr

Luther F. Warren, Professor of Medicine at the Long Island College Hospital Medical School, gave a talk on "Heart Disease in Pregnancy from a Medical Viewpoint." He based his remarks on studies made in the obstetrical and medical wards of the hospital and showed that pregnancy was not necessarily such a fatal condition as it has been supposed.

Dr C. Floyd Haviland, former chairman of the Hospital Commission, and now Superintendent of the Manhattan State Hospital on Ward's Island, gave a paper on "Psychiatry and the General Practitioner." He made a plea that men in general practice should study the elements of diagnosing abnormal mental states in their incipency. He offered to cooperate in developing a method of presenting the principles of psychiatry to physicians in a simple form.

health officers and doctors. This problem is happily not acute in New York State where health officers are necessarily physicians, but yet the general practitioner could well take a much greater interest in the work of the health officer.

"There is a grave danger that laymen will get ahead of doctors in public health work. The natural stimulation of the doctors would come from the A M A, through the state societies, down to the county medical societies. Diphtheria, for example, could be eradicated by a unified, intensive campaign under the joint auspices of the A M A and the A P H A, and subordinate groups."

Dr Louis I Harris, Chairman of the Section on Public Health Administration and Commissioner of Health of New York City, said:

"The most important problem that came before the section was that of isolations in the several communicable diseases, especially those classed as minor. A committee had investigated the problem from all angles, and had submitted a report whose reading took two hours. Some radical changes were suggested, largely along the lines of a less severe form of isolation. The section was almost evenly divided over the question of immediately adopting the report. Some felt that since the causes of many of the diseases were still unknown, the old, tried methods should be continued until more definite knowledge was available. Some felt that to adopt sweeping changes all at once would be construed by the public as a confession of past inefficiency that would be used by cultists and quacks to discredit the medical profession. It would seem best to adopt any necessary changes gradually so as to preserve the widespread uni-

formity of procedure that is now observed."

The relation of physicians to other public health workers, or rather an interpretation of that relation, was revealed in an unexpected way at a luncheon conference of editors of health magazines at which the editor of a medical journal which was the organ of a state medical society was introduced as somewhat of an interloper in the group, since he was a physician and edited a journal for physicians. Dr Haven Emerson, head of the Department of Public Health of the College of Physicians and Surgeons, New York City, warmly defended the medical editor and said:

"When a public health movement or campaign is started, there is a standard order of procedure to be followed:

"1 Develop a definite statement of the object to be attained

"2 Devise a definite plan of procedure

"3 Go to the proper organization of physicians and discuss the plan with the members of the medical society. Modify the plan in accordance with the wishes and experience of the physicians, and get their support and participation before taking any further steps. The assistance of the practising physicians is essential in any modern public health movement.

"4 When the approval of the physicians has been secured go before selected groups and state the plans. Such groups would include school teachers, ministers, churches, chambers of commerce, and boards of health.

"5 After all these preliminary steps have been taken, then and then only, start a general campaign of publicity and education through the newspapers."

THE ANNUAL CONFERENCE OF HEALTH OFFICERS

The twenty-fifth annual conference of health officers of New York State was held in the Hotel Statler, Buffalo, on October 12, 13 and 14, jointly with the annual conference of public health nurses.

The conference was made an integral part of the annual meeting of the American Public Health Association, and its program of Tuesday October 12, was given over to the State conference. The annual meeting of the Eighth District Branch of the Medical Society of the State of New York was also listed on the general program of the American Public Health Association, but the meeting of the District Branch had no physical connection with that of the public health workers.

The plan of holding the conference of special public health workers jointly with the meeting of the American Public Health Association had its disadvantages as well as advantages. It was

a disadvantage to the health officers and nurses that the individuals were separated from one another in the hotels and meetings, and they missed the comradeship that came from gathering together in one hotel, eating in the same dining room, and congregating on the big porches and in the spacious corridors of the Grand Union Hotel in Saratoga where the conference has usually been held. (See the description of the 1925 conference on page 872 of the August, 1925, issue of this JOURNAL.)

On the other hand, the meeting of the American Public Health Association afforded the opportunity for the health officers and nurses to meet the prominent public health workers from all over the United States and Canada on a social basis, and to hear them discuss the same problems that are agitated in New York State. One is deeply impressed with the immensity and the importance of public health problems, and

WASHINGTON COUNTY SEMI-ANNUAL MEETING

The semi-annual meeting of the Washington County Medical Society was held on May 11, 1926, in Fort Edward with President Prescott in the chair and twenty-two members and four visitors present

Dr Banker, the Secretary, reported on a meeting of the Comitia Minora held on April 6, when the matter of financing a course of graduate lectures was discussed. On motion each member of the society was assessed one dollar in order to defray the expenses of a lecture course

The following resolution was adopted and ordered sent to the Board of Supervisors

WHEREAS, the Washington County Public Health Clinic as given excellent service, to the doctors of the county on the early diagnosis of tuberculosis, and

WHEREAS, the physicians in charge have materially assisted in the work, therefore be it

Resolved, that the Board of Supervisors be requested to continue the clinic without interruption in the interest of the health of the people of the county

On motion the president was asked to name a committee to revise the fee list

After a social luncheon at noon, the society met in the Baptist Church for a scientific session

The vice-president gave an address on "The Trend of Modern Medicine" calling attention to the civic work of physicians and advising periodic examinations

Dr Vickers read a paper on "Eponyms of Anatomy"

Dr Albert Pfeiffer, Director of the Division of Venereal Diseases of the State Department of Health showed a series of lantern slides on "The Early Diagnosis and Treatment of Syphilis" with special reference to heart disease

Dr L W Gorham gave a lecture on "Liver Functions" illustrated with lantern slides

A vote of thanks was given to the Rev Mr Myers for the use of the church auditorium and lantern

The society voted to oppose Federal Bill Number 4085 amending the narcotic law

During the past three years the average attendance at the meetings has been seventeen. Only four members have not attended any meeting and one of these was present twice at the Glens Falls lecture course.

WASHINGTON COUNTY ANNUAL MEETING

The annual meeting of the Washington County Medical Society was held at Hudson Falls, October 5, 1926, at 4 30 o'clock, with 22 members present. The following officers were elected for the ensuing year

President, C A Prescott, M D, Vice-President, S T Fortune, M D, Secretary, S J Banker, M D, Treasurer, R C Paris, M D, Censors, P C Tillotson, M D, L M White, M D, I M Schneible, M D, Committee on Legislation, W A Leonard, M D, G M Stillman, M D, H S Blackfan, M D

The treasurer reported a balance of \$16 98 on hand

On motion, it was voted to assess the members one dollar for the year 1927, in addition to the dues, with the intention that the by-laws be changed to make the annual dues two dollars

Dr Munson presented the subject of the expenditure of the funds received from the sale of red cross seals. After much discussion, it was voted that we recommend that the committee employ a county nurse, to be paid out of this fund.

The president, Dr M A Rogers, gave the

annual presidential address, "The Office Treatment of Endocarditis"

The members dined together at the Carleton. After the dinner, Dr Joseph S Lawrence spoke at length as to what the duties of a county society should be and emphasized the importance of these duties to the profession and to the community they served

The members then adjourned to the Court House for an evening session. Dr Frank W Sulzman of Troy presented his paper on the "Relation of the Tonsils to Systemic Infection". He emphasized the importance of distinguishing between the infected tonsil that should be removed and the non-infected that should not be removed

Dr James F Rooney, of Albany, presented the subject of "Carcinoma of the Stomach," recommending the use of radium and X-ray as palliative measures

Dr Paul B Brooks, Deputy Health Commissioner of New York State, spoke at length on the change in the practice of medicine in the past few years which had been brought about by public health measures, and advised that the general practitioner endeavor to do more work along the line of preventive medicine

NEWS NOTES

NINE THOUSAND DOCTORS HAVE REGISTERED—HAVE YOU?

Dr Harold Rypins, Secretary of the Board of Medical Examiners, reports that about 9,000 physicians had registered up to October 15, and that about 7,000 more should send their applications.

So far only one doctor has made a complaint. One physician entered a protest against the fee and the abuse of the vested rights of doctors, and the imposition of another form of "graft."

A large number of physicians have entered the State too late to be recorded in the Directory. Many of the doctors who have taken the State examination since January 1, 1926, gave addresses from hospitals and boarding-houses, and their present addresses are unknown to the Regents.

Cards have not been sent to those in the two groups, because their addresses are unknown.

Pass the word to those who have not received cards from the licensing board and tell them to apply for the blanks. Write to the Board of Medical Examiners, State Department of Education, Albany, N Y.

Dr Rypins also reports that the machinery of the Board of Regents is in operation for proceeding against illegal practitioners. Two convictions have already been secured and complaints have been prepared against six or eight other offenders. The operation of the code of criminal procedure in New York State is unusually slow and permits the accused to avail themselves of long notices and delays. Prosecutions will therefore be slow and will lack spectacular features.

Four inspectors are giving their full time to the investigation of complaints, and the number of prospective cases is large. However, many illegal practitioners against whom evidence has been sought have moved out of the State.

Many cases have also been referred to the Grievance Committee without charges being prepared, or publicity made which would be to the detriment of innocent physicians.

Altogether, the new Practice of Medicine Act has been put into active operation, and is functioning with efficiency.

IMMUNIZATION AGAINST DIPHTHERIA

The campaign for immunizing all the children of New York State against diphtheria is being well supported by the physicians of New York State. An increasing number of county medical societies have endorsed the movement and are carrying on active campaigns to induce the physicians to give toxin-antitoxin to the children of the families whom they treat. The following notes from the field have been received.

The Broome County Medical Society has appointed the following committee to instruct the public in the eradication of diphtheria and the possibility of wiping out the disease: Drs. H I Johnston, Chalmers J Longstreet, the health officer of Binghamton, Henry C Sears and M S Bloom. The committee has taken steps to induce parents to permit the immunization of children against the disease. They have urged all parents to take their children either to their family physician or to the nearest child welfare clinic or to the high school clinic, where physicians will be in charge.

The Diphtheria Committee of the Schenectady County Medical Society states that excel-

lent progress has been made both in the city and in Schenectady county in the effort to eradicate diphtheria through the use of Toxin-Antitoxin, and not only are parents promising cooperation in the movement but local physicians have reported that requests for Toxin-Antitoxin injections have been extremely numerous within the last two weeks. The Committee is cooperating with other public health agencies operating in the city and county and has been considerably aided by the Girl Scouts, who have prepared a list of approximately 10,000 small children and their addresses and age. The parents of more than 3,000 of these children have been visited by the city and county nurses.

The following immunization clinics against diphtheria were held during the last week of September.

At the high school building in Warrensburg, Warren county, by Drs J E Goodman and P H Huntington, in Monterey, Schuyler county, by Drs S B Clark and O A Allen, at Moreland Grange, Schuyler county, by Drs J M Quirk and O A Allen.

scribing and advocating a secret remedy for cancer whose nature he refuses to divulge

The Scientific session opened with an address by Commissioner Louis I Harris, M D, on "The Medical Profession and Public Health" He spoke of the relation of the medical practitioner to the Department of Health, stating that the examination of millions of school children in New York City by the Health Department can be no more than a mere gesture because of the Department's lack of knowledge of each child's home life and past He expressed the wish for the time to come when the request for funds for the examination of children, excepting those of the downright poor, could be eliminated from the budget, and emphasized that such examinations should be made by family physicians The activities of the Health Department should be more especially directed to research work tracing diseases to their sources and should not be charged with duties that might better be done by private physicians Concentration of effort in behalf of children of pre-school age was urged by the Commissioner and he cited some of the activities of the Health Department along these lines, including research work to produce a preventive serum to combat measles Such work promised a rich field of endeavor and would result in a reduction of cardiac and other diseases which develop later in life He advocated mental hygiene among children of the pre-school periods, declaring that many of the criminals of today could have been recognized before criminal tendencies had brought them to trouble, had intelli-

gent diagnoses been made in early life

Speaking of the study of disease in the adolescent child, the commissioner said that latent diseases were aroused by improper conditions, in which the adolescent child, employed industrially, worked and lived He warned against the "quack" practitioner active at the present and a menace to the legitimate profession "The voice of the quack, the voice of the charlatan, is loud in our midst, but it must not be heard" Medical men need not be afraid of heralding the truth

Dr Ernest Loewenstein addressed the Society on "The Ambulatory Treatment of Tuberculosis"

Following the Scientific session the secretary presented to the Society a statement of the activities under the auspices of the State Medical Society to eradicate diphtheria and presented the following resolution, which was adopted —

Whereas, the Medical Society of the County of Queens is cognizant of a state-wide movement to eradicate diphtheria from the communities of this state, the movement consisting of instruction of the people in the differentiation of individuals into those susceptible and non-susceptible to the disease, in the value of toxin-antitoxin as a practical and effective measure to immunize those who are susceptible, and, in the value of such immunization as a measure to eradicate this disease

Therefore be it resolved, that the Society endorses the state-wide movement to eradicate diphtheria and to endorse the ideal, "No more diphtheria by 1930"

ONONDAGA COUNTY MEDICAL SOCIETY

At the opening meeting of the season of the Onondaga County Country Club on the evening of Tuesday, October 5th, although the evening was stormy, over 150 members were present

After routine business had been transacted, Dr Dean Lewis, Professor of Surgery in the Johns Hopkins Medical School, gave a paper

on "Tumors of Bone" He illustrated his talk with a series of lantern slides of tumors of both common and rare forms He brought together a wealth of facts regarding bone conditions which any physician is likely to meet, but which are not described in a readily accessible form

ST LAWRENCE COUNTY MEDICAL SOCIETY

The annual meeting of the St Lawrence County Medical Society was held on Tuesday, October 5th, at Curtis Hall, St Lawrence State Hospital The retiring President, Dr J P O'Brien, of Louisville, presided and delivered an address on "Post-Graduate Medical Education in St Lawrence County" Dr T A Lewis, of Hammond, Vice-President, led in the discussion of the paper

The scientific program consisted of a paper by Dr R J Reynolds of Potsdam, on "Physio-

therapeutic Measures Which Have Value for the General Practitioner," and a paper by Dr T S Barnet of Potsdam, on "A Brief Discussion of Gwathmey's Method for Painless Childbirth"

Forty members were in attendance At the business meeting the following officers were elected

Vice-Pres—J A Lewis, Hammond
Secretary—S W Close, Gouverneur
Treasurer—C T Henderson, Gouverneur
President—R J Reynolds, Potsdam

ANNUAL MEETING COLUMBIA COUNTY MEDICAL SOCIETY

Annual meeting Columbia County Medical Society was held at the Worth House, Hudson, N Y, Tuesday, October 5, 1926, the President, H J Noerling, presiding

Members present — Drs Collins, Conklin, Deane, Diefendorf, Early, Edwards, Garnsey, King, Mambert, Maxon, McCormack, Nichols, C G Rossman, G W Rossman, Skinner, Taylor, Van Hoesen, Wheeler, Wilson Guests — Dr McCabe, President District Branch, and Dr Van der Veer, Albany

The following officers for coming year were duly elected President, Dr J W Mambert, Vice-President, Dr Burke Diefendorf, Secretary and Treasurer, Dr C R Skinner Censors Drs Van Hoesen, C G Rossman, Collins, Garnsey, Maxon Delegate to State Society Dr C L Nichols Alternate Delegate Dr H J Noerling

Dr King referred to lack of records of Society from 1863 to 1904, and requested the secretary to collect such data and include it in the records of the Society On motion, the secretary was instructed to comply with the request

Dr Noerling called attention of the Society to the recent death of Dr I C Washburn of Chatham On motion, Drs Maxon, Rossman, and Skinner were appointed a committee to draft resolutions upon the death of Dr I C Washburn of Chatham

The following resolution was then offered and approved by the Society

Whereas, in the death of Dr I C Washburn, the Columbia County Medical Society deeply appreciates the loss of his membership and wishes to record its sentiment of affection and regard,

THEREFORE, BE IT RESOLVED, That there be recorded upon the minutes of this Society public acknowledgment of appreciation of the life, works, and kindly deeds of Dr Washburn, and that the condolences of the Society be extended to his bereaved family

There was considerable discussion upon the advisability of appealing to the County Board of Supervisors for an appropriation to establish a County Public Laboratory Moved that the committee be instructed to obtain full data upon this subject, and that a special meeting of the Society be called for discussing the findings, before November 15 Carried

The following committees were appointed
Post-Graduate Education and Public Health
Drs Whitbeck, Galatin, Wheeler, Collins and Garnsey

Legislature Drs Rosenau, Van Hoesen, Noerling, Mason and Nichols

After luncheon, the Society reconvened with President-elect Mambert presiding, and conducted the following scientific program

Address, Dr H J Noerling

The Use of Insulin in Surgical Conditions, by Dr Edgar A Van der Veer of Albany

Dr Van Hoesen then spoke on Gas Infection with Special Reference to Antitoxic Serum

QUEENS COUNTY MEDICAL SOCIETY

A regular meeting of the Medical Society of the County of Queens was held at the Queens Valley Golf Club on September 28, 1926, in conjunction with the annual meeting of the Queensboro Tuberculosis and Health Association Attendance 80

At 6 30 P M a dinner was tendered in honor of Hon Louis I Harris, Commissioner of Health, City of New York, by the Queensboro Tuberculosis and Health Association in which the members of the County Medical Society participated

At 9 00 P M the Society convened in Executive Session The minutes of the June meeting were approved as published

Dr T C Chalmers reported for the Comitia Minora and recommended the following candidates, who were unanimously elected to membership, by ballot cast by the Secretary

T F Draper, M D, Jericho Turnpike and 220th Street, Queens Village

Carimir J Jarka, M D, 147-49 Arlington Terrace, Jamaica, L I

Coleman R V King, M D, 103-36 Lefferts Avenue, Richmond Hill, L I

Henry Kulmeyer, M D 9305 Woodhaven Boulevard, Woodhaven, L I

Thomas E Larkin, M D, 9011 196th Street, Hollis, L I

William H Nafis, M D, 300 Ascan Avenue, Forest Hills, L I

Morris Sternberg, M D 1010 Seneca Avenue, Ridgewood, Brooklyn

Robert R Yanover, M D, 9531 Roosevelt Avenue, Elmhurst, L I

The following were received by transfer

John Sherburne, M D, 8159 Lefferts Avenue, Kew Gardens, L I, from the Montgomery County Medical Society

John Archibald Smith, M D 200 25th Street, Jackson Heights, L I, from the Medical Society of the County of Franklin, as of January 1, 1926

Dr T C Chalmers then reported for the Board of Censors regarding charges against one of the members of the Society for pre-

scribing and advocating a secret remedy for cancer whose nature he refuses to divulge

The Scientific session opened with an address by Commissioner Louis I Harris, M D, on "The Medical Profession and Public Health" He spoke of the relation of the medical practitioner to the Department of Health, stating that the examination of millions of school children in New York City by the Health Department can be no more than a mere gesture because of the Department's lack of knowledge of each child's home life and past. He expressed the wish for the time to come when the request for funds for the examination of children, excepting those of the downright poor, could be eliminated from the budget, and emphasized that such examinations should be made by family physicians. The activities of the Health Department should be more especially directed to research work tracing diseases to their sources and should not be charged with duties that might better be done by private physicians. Concentration of effort in behalf of children of pre-school age was urged by the Commissioner and he cited some of the activities of the Health Department along these lines, including research work to produce a preventive serum to combat measles. Such work promised a rich field of endeavor and would result in a reduction of cardiac and other diseases which develop later in life. He advocated mental hygiene among children of the pre-school periods, declaring that many of the criminals of today could have been recognized before criminal tendencies had brought them to trouble, had intelli-

gent diagnoses been made in early life

Speaking of the study of disease in the adolescent child, the commissioner said that latent diseases were aroused by improper conditions, in which the adolescent child, employed industrially, worked and lived. He warned against the "quack" practitioner active at the present and a menace to the legitimate profession. "The voice of the quack, the voice of the charlatan, is loud in our midst, but it must not be heard." Medical men need not be afraid of heralding the truth.

Dr Ernest Loewenstein addressed the Society on "The Ambulatory Treatment of Tuberculosis"

Following the Scientific session the secretary presented to the Society a statement of the activities under the auspices of the State Medical Society to eradicate diphtheria and presented the following resolution, which was adopted—

Whereas, the Medical Society of the County of Queens is cognizant of a state-wide movement to eradicate diphtheria from the communities of this state, the movement consisting of instruction of the people in the differentiation of individuals into those susceptible and non-susceptible to the disease, in the value of toxin-antitoxin as a practical and effective measure to immunize those who are susceptible, and, in the value of such immunization as a measure to eradicate this disease

Therefore be it resolved, that the Society endorses the state-wide movement to eradicate diphtheria and to endorse the ideal, "No more diphtheria by 1930"

ONONDAGA COUNTY MEDICAL SOCIETY

THE DAILY PRESS

LOUISA LEE SCHUYLER

Miss Louisa Lee Schuyler, who founded the State Charities Aid Association in 1872, died on October 10, aged 89 years, less sixteen days. She was a descendant of both General Philip Schuyler and Alexander Hamilton, and inherited the civic instincts of both ancestors. It is interesting that her first inspiration in social service came from Dr Willard Parker. The *New York Times* of October 11 relates the incident:

"Miss Schuyler's grandmother fell and broke her arm. Dr Willard Parker, the famous New York surgeon, was called in and spent the night at the house. After dinner, as the family and physician sat around the wood fire, Dr Parker told some of his experiences in hospitals. Then, after a pause he turned to the ladies present and said:

"I wish some of you ladies would visit those hospitals when you come to town. I asked a poor, bedridden Irishwoman today, who had been there several years, whether she was being taken care of. 'Oh, yes, doctor,' she replied, 'the doctors and nurses are very kind but they are very busy, and I have no friends to come and see me. So I just lie here all day long with no one to talk to, year in and year out, and the time seems long, very long.'"

Following her experiences in Bellevue Miss Schuyler worked with the United States Sanitary Commission, the precursor of the Red Cross, during the Civil War. She founded the State Charities Aid Association on May 11, 1874, in the home of her parents at 19 West Thirty-first Street, New York, and in 1874 she established a training school for nurses in Bellevue Hospital—the first in the United States.

Miss Schuyler received the honorary degree of LL.D. from Columbia University in 1915, at which time President Butler made this citation:

"A pioneer in the service of noble women in this State, founder of the State Charities Aid Association and the system of visitation of State institutions by volunteer committees, originator of the first training school for nurses, initiating and successfully advocating legislation for the State care of the insane, powerfully aiding the first movement for the prevention of blindness in little children, worthy representative of a long line of ancestors distinguished through centuries for manifold services to the city, state and nation."

The *New York Times* of October 11 has an editorial on her life, closing with these words:

"Had she been born a generation later, she might easily have become a great political leader. She was in reality such a leader in the cause of the sick and the poor, but a Deborah who stirred the Baraks, the men officials and bosses, to do what she as a woman was not in her day free to do. She is the last as she was the greatest of that group of noble women who thirty years ago transformed New York's philanthropy."

Physicians are interested in the life of Miss Schuyler because she was the founder of the laymen's part of the Trinity of Public Health organizations which also includes the medical societies and the official departments of health. It is interesting to note that lay organizations existed for a decade before they were able to persuade the office holders and law makers to establish official departments of health supported by the taxpayer's money.

NEGRO DOCTORS IN THE ANTI-TUBERCULOSIS WORK

The *New York Tribune* of October 4 contains an abstract of a report of the anti-tuberculosis work of Henry Phipps Institute among the negroes of Philadelphia. It brings out the opinion of the Director of the Institute that negro physicians and nurses are essential in combatting tuberculosis among colored people. The article says:

"The reports, compiled for the institute's advisory council of prominent physicians, scientists and educators, show that, while fewer than 100 negroes a year applied for treatment in the institute when work among their race was carried on

exclusively by white agencies, the total now has reached more than 2,600 annually since the employment of negro doctors and nurses.

"This work, although originating at the institute, has been developed in three other localities in the city. It is supported by the Philadelphia Health Council and the Whittier Center Association.

"Not only were 1,885 new cases among negroes listed last year and 794 patients reinstated, but in addition 10,200 dispensary visits were recorded, 8,943 examinations made by doctors and 12,726 visits made by nurses working among the negro patients outside the institute."

"These records show," Dr Hatfield said, "that preventive work among negroes can best be carried out by negro physicians. Indeed, I do not believe that it can be done effectively otherwise. If this is to be made possible, however, means will have to be obtained to provide scholarships for the training of these men. To a lesser degree this also is true of the colored nurse."

The Phipps Institute for the Study, Treatment and Prevention of Tuberculosis, which was founded by Henry Phipps, of New York, in 1903, and has since been aided materially by contributions from the Phipps family, is unique in its field in that it combines under one roof laboratories for research, dispensaries, and wards for the care of tuberculosis patients. It is now conducted

with the cooperation of the entire medical group of the University of Pennsylvania.

It has been the opinion among physicians that colored people have more confidence in white physicians than in those of their own race. But there is an emotional element to be considered. To the educated negro physicians and nurses are ascribed a mysterious power that comes from their unusual knowledge, and if they look wise and are sympathetic, their advice will be followed eagerly when that of a white doctor will be ignored. At any rate, it is wise to make further use of colored nurses in anti-tuberculosis work among negroes, among whom white nurses are often regarded with suspicion.

PROGRESS IN MENTAL CAPACITY

The *New York Times* of October 15 records an address given by Professor Robert A. Millikan at Yale University on the subject, "New Truth and Old," in which he says:

"The more intimately one gets in touch with any civilization of bygone days, the more he is struck by the similarity between the way people lived and talked two or three thousand years ago and the way they live and talk and think now."

"The beauty of women, the strength of men, the flavor of strawberries, the aroma of flowers, the love of friends, courtship, marriage and divorce, the racetrack, the wrestling match and the boxing bout, all of these played almost exactly the same role in the lives of the people of Rome as they play in the lives of the people of New Haven or New York. And it is around these things, too, that about 90 per cent of the interests of the average man revolve."

"Not even in what are called the higher things in life, can we be truthfully said to have made, or to be making any real progress. That question has often been raised, and often answered negatively by literary men of reputation, sometimes even by philosophers, and occasionally also by divines."

"In devotion to moral and spiritual ideals, where can the twentieth century show anything finer than the death of Socrates? And was it not 2,000 years ago in Galilee that One lived of whom the whole thinking world still says, 'Never man spake as this man'?"

The idea that man's mental capacity is the same today that it was several thousands of years ago might seem contradictory to the progress of mankind, physically, morally, and spiritually. Man's progress has been in his environment rather than in man himself. But the idea that man himself has remained unchanged requires some explanation.

What is the standard of measurement of mental capacity? A standard that is readily understood is that of mental age. Statistics show that about 25 per cent of the people of the United States have the mental capacities of children under 12 years of age. The average mentality of the people is that of a child of 14 years. Only 4 per cent have the superior mental capacity which is attained by bright students well prepared for college.

The world has always been dominated by the few of great mental capacity. The race that contains many capable leaders will overcome and annihilate the races of inferior mental capacity. The Anglo-Saxon nations have had an abundance of gifted men throughout the entire period of their history, and this large proportion of outstanding leaders has enabled them to establish and sustain world-wide empires. Yet the subjugated races have often produced a few men whose mental capacities have equalled those of the best Anglo-Saxons.

While men of genius do not seem to be more capable now than they were thousands of years ago, yet their proportion among civilized people is enormously increased, and the reason is simple. The gifted leaders married into the families of other leaders, and those of superior mental capacities survived in greater numbers than those who were unable to meet dangers or to dominate cold, and storm, and wild beasts, and still wilder men. There were a few men of genius ten thousand years ago who had the mental capacity of the genius of today, and those men were the progenitors of the leaders of today. Modern leaders are the same today that they were ten thousand years ago, and the same is true of the great mass of men who are below the average mental capacity of the race.

BOOKS RECEIVED

Acknowledgment of all books received will be made in this column and this will be deemed by us a full equivalent to those sending them. A selection from this column will be made for review, as dictated by their merits, or in the interests of our readers

- MEDICAL GYMNASICS AND MASSAGE IN GENERAL PRACTICE.** By Dr J Arvedson Second edition. Translated and edited by Mina L. Dobbie, M.D. 12mo of 284 pages Philadelphia, P Blakiston's Son and Company, 1926 Cloth, \$2 50
- GOULD'S MEDICAL DICTIONARY** Containing All the Words and Phrases Generally Used in Medicine and the Allied Sciences, With Their Proper Pronunciation, Derivation, and Definition By George M. Gould, A.M., M.D. Edited by R. J. E. Scott, M.D. Octavo of 1,398 pages, with illustrations and tables Philadelphia, P Blakiston's Son and Company, 1926 Flexible leather, \$9 00
- A MANUAL OF PROCTOLOGY** By T Chittenden Hill Ph.B., M.D. Second edition, thoroughly revised. 12mo of 294 pages, with 101 illustrations Philadelphia and New York, Lea and Febiger, 1926 Cloth, \$3 50
- A LABORATORY MANUAL FOR ELEMENTARY ZOOLOGY** By Libbie Henrietta Hyman (Second Edition) Octavo of 182 pages Chicago, Illinois, The University Press, 1926. Cloth, \$2 50
- A GUIDE FOR DIABETICS** By Walter R. Campbell, M.A., M.D., and Mame T. Porter, B.Sc. Octavo of 259 pages Baltimore, The Williams & Wilkins Company, 1926 Cloth, \$2 50
- ESSAYS IN THE HISTORY OF MEDICINE.** By Karl Sudhoff, M.D. Translated by various hands and edited, with foreword and biographical sketch, by Fielding H. Garrison, M.D. Octavo of 397 pages New York, Medical Life Press, 1926 Cloth, \$5 00
- THE ESCAPE FROM THE PRIMITIVE.** By Horace Carncross, M.D. Octavo of 348 pages New York and London, Charles Scribner's Sons, 1926 Cloth, \$2 50
- PRACTICAL DIETETICS FOR ADULTS AND CHILDREN IN HEALTH AND DISEASE.** By Sanford Blum, A.B., M.S., M.D. Second revised edition. Octavo of 362 pages Philadelphia, F. A. Davis Company, 1926 Cloth, \$4 00
- DEFECTIVE MEMORY, ABSENTMINDEDNESS AND THEIR TREATMENT** By Arnold Lorand, M.D. Octavo of 340 pages Philadelphia, F. A. Davis Company 1926 Cloth, \$3 00
- A PRACTICE OF PHYSIOTHERAPY** By C. M. Sampson, M.D. Octavo of 620 pages, with 146 illustrations St. Louis, The C. V. Mosby Company, 1926 Cloth, \$10 00
- THE SURGICAL TREATMENT OF GOITRE** By Willard Bartlett, A.B., A.M., M.D. Octavo of 365 pages, with 130 illustrations St. Louis, The C. V. Mosby Company, 1926 Cloth, \$8 50
- OUR MINDS AND THEIR BODIES** By John Laird 12mo of 122 pages London and New York, Oxford University Press, 1925 Cloth, \$1 00
- A TEXTBOOK OF THE PRACTICE OF MEDICINE.** By various authors Edited by Frederick W. Price, M.D. Second edition. Octavo of 1828 pages London and New York, Oxford University Press, 1926. Cloth, \$10 00 (Oxford Medical Publications.)
- I BELIEVE IN GOD AND IN EVOLUTION** By William W. Keen, M.D. Fourth Revised Edition, 12mo of 109 pages, illustrated. Philadelphia and London, J. B. Lippincott Company, (1925) Cloth, \$1 25
- A MANUAL OF THE PARASITIC PROTOZOA OF MAN** By Charles F. Craig, M.D., M.A. Octavo of 569 pages, illustrated. Philadelphia and London, J. B. Lippincott Company, 1926
- MEDICAL CLINICS OF NORTH AMERICA.** Vol 10, No 2 September, 1926 (Philadelphia Number) Published every other month by the W. B. Saunders Company, Philadelphia and London. Per Clinic Year (6 issues) Cloth, \$16 00 net, paper, \$12 00
- PLASTIC SURGERY OF THE HEAD, FACE AND NECK** By H. Lyons Hunt, M.D., L.R.C.S. Octavo of 404 pages, illustrated with 342 engravings and 10 colored plates Philadelphia and New York, Lea and Febiger, 1926. Cloth, \$7 00
- WHAT'S BEST TO EAT?** By S. Henning Belfrage, M.D., M.R.C.S., L.R.C.P. With a Practical Supplement by Lucy H. Yates, M.C.A. Octavo of 199 pages New York, William Wood and Company, 1926 Cloth, \$3 00
- THE INFLAMMATORY AND TOXIC DISEASES OF BONE.** A Text-Book for Senior Students By R. Lawford Knaggs, M.C., F.R.C.S., with numerous photomicrographs by C. H. Rodman, M.D. Octavo of 416 pages, 197 illustrations. New York, William Wood and Company, 1926 Cloth, \$5 50.
- FRESHMAN HYGIENE.** Personal and Social Problems of the College Student By Raymond C. Bull, A.B., M.D., and Stanley Thomas, M.S., M.A. Octavo of 288 pages with 74 illustrations Philadelphia & London, J. B. Lippincott Company, 1926 Cloth, \$2 00
- RHEUMATISM, Its Meaning and Its Menace.** By Lewellys F. Barker, M.D. and Norman B. Cole, M.D. 12mo of 165 pages New York, London, D. Appleton and Company, 1926 Cloth, \$1 50
- METHODS AND PROBLEMS OF MEDICAL EDUCATION** Fifth Series Division of Medical Education, The Rockefeller Foundation, New York City, 1926 Quarto of 225 pages
- A PRACTICAL MEDICAL DICTIONARY** By Thomas Lathrop Stedman, A.M., M.D. Ninth Edition. Octavo of 1178 pages, illustrated New York, William Wood and Company, 1926 Flexible leather, \$7 50
- WERK UND WIRKUNG—Eine Vortragsreise.** Von Professor Dr. Hans Much. 12mo of 227 pages, illustrated Leipzig, Curt Kabitzsch, 1926 Paper, Marks 7.20 (Moderne Biologie, Heft 11)

BOOK REVIEWS

MANUAL OF EMERGENCIES MEDICAL, SURGICAL AND OBSTETRIC. Their Pathology, Diagnosis and Treatment. By J SNOWMAN, M.D., M.R.C.P., Lond. Second Edition. 12mo of 361 pages. New York, William Wood and Company, 1926 Cloth, \$4.00

The first edition of this manual published in 1919, was based upon the English Edition of Lenzmann's "Emergencies" which appeared in 1914, and this latest edition is presented with extensive revision and numerous additions, representing the modern teachings in Pathology, Diagnosis and Treatment of the British Medical mind. The subject matter is in condensed form, and so quite readily available for the immediate demand. While some of these teachings may not fit in with the ordinary conceptions of the American physician, it is well for breadth of mind to learn how others are doing things and solving emergencies. A careful reading of this work will aid in getting one out of a too well worn rut. This is a useful and handy volume in time of anxiety.

ROGER DURHAM

GOULD AND PYLE'S POCKET CYCLOPEDIA OF MEDICINE AND SURGERY Based upon the Fourth Edition of Gould Pyle's Cyclopaedia of Practical Medicine and Surgery Third edition. Revised, enlarged and edited by R. J. E. SCOTT, M.A., B.C.L., M.D. 16mo of 922 pages. Philadelphia, P. Blakiston's Son and Company, 1926 Flexible binding, \$2.00, with thumb index, \$2.50

The fact that this pocket cyclopaedia is now in its third edition proves its usefulness. Nine hundred and twenty-two pages of classified information, without an unnecessary word, is printed clearly in small, but readable, type upon thin paper, giving us a volume only one inch in thickness and small enough to fit into the coat pocket. Obsolete or useless information has no place in this book which is comprehensive in its contained information from Abasia to Zoster. Many condensed tables are found throughout the volume and at the end we find a dose table for drugs, official and non-official. The information in this book is accurate and useful for one who hurriedly wants to review any subject briefly.

H. M. M.

GASTRIC FUNCTION IN HEALTH AND DISEASE. By JOHN A. RYLE, M.D., F.R.C.P. Octavo of 152 pages, with illustrations. New York, Oxford University Press, 1926 Cloth, \$2.75 (Oxford Medical Publications.)

In the past year English gastro-enterologists have suddenly burst forth in a very entertaining if not always scientific array of books on the important subject of diseases of the stomach. This small work is one of the best of these that we have seen. The book is well planned, being divided into three parts, each of which is concluded with a summary and a list of references. The first part, on "Gastric Function in Health," is by far the best, and presents a very clear picture of the modern ideas in regard to this subject. Carlson's work is frequently referred to, and the importance of Reh-fuss' fractional method of gastric analysis in studying gastric function is emphasized. Part II on "Gastric Functions in Disease," takes up the subject in a general way, and attempts to explain the various symptoms of gastrointestinal diseases in a logical manner, although the author is apparently not familiar with Alvarez's researches in gastrointestinal motility, which explains many of the points the author says are still in dispute. In the third part, after explaining that the term "dyspepsia" is of no more significance than "dyspnea," the author goes on to classify "the Dyspepsias" in truly

English fashion, into five groups—habit, nervous, toxic, irritative and mechanical types. Why is it that all English authors will insist on classifying a group of symptoms? Imagine a book devoted to "The Dyspneas"! A final chapter discussing the disturbed functions following gastro-jejunostomy, is well worth reading. A.

THOMAS SYDENHAM, CLINICIAN By DAVID RIESMAN, M.D. 12mo of 52 pages. New York, Paul B. Hoeber, Inc., 1926 Cloth, \$1.50

If Paul B. Hoeber, Inc., have done nothing else to attain immortality in the world of medical tomes their books dealing with various phases of medical history and medical personality places them in an advantageous position to have such a distinction become a reality. Along with the Annals of Medical History (unfortunately known to but a handful of physicians in this country) every little while a new volume, historical in theme, makes its bow.

This latest gem, "Thomas Sydenham, Clinician," is a small book of but fifty-two pages. Just of sufficient length to read before switching off the bed-light. Professor Riesman has compacted essential facts within a small space and has lost nothing in so doing. From a literary angle every page reveals the charm of the author's pen. Every physician will profit by reading this very brief journey to the first great medical clinician.

Hoeber, Inc., as usual, have made it into a beautiful volume. But then, Hoeber, Inc., do do fine books and they should be encouraged in attempting the unusual and fascinating in medical publishing by doctors at large showing their appreciation by adding to their libraries. We sincerely recommend "Thomas Sydenham, Clinician."

T. S. W.

THE ASPERGILLI. By CHARLES THOM and MARGARET B. CHURCH. Photomicrographs by G. L. KEENAN. Octavo of 272 pages. Baltimore, Williams and Wilkins Company, 1926 Cloth, \$5.00

This book will be of interest chiefly to botanists, bacteriologists and food investigators and of limited interest to physicians. The Aspergillus group constitutes a very large percentage of the molds found in foodstuffs, soil and in various industries, in some of which they serve a useful purpose, in others are troublesome invaders or are actually harmful. From time to time, aspergilli have been described as the cause of skin, respiratory and other diseases in man and animals.

The authors have had a long experience in microbiology and have produced an exceedingly complete summation of knowledge of these molds.

Part I is a discussion of the general morphological, physiological, biochemical and pathological characteristics of the aspergilli with directions for their cultivation.

Part 2 is devoted entirely to nomenclature, classification and description of forms.

E. B. SMITH

OUR TIMES The United States 1900-1925 Vol. 1 The Turn of the Century. By MARK SULLIVAN. Octavo of 610 pages, with illustrations. New York and London, Charles Scribner's Sons, 1926 Cloth, \$5.00

To those of us who have passed forty years this volume of Mark Sullivan's not only intrigues and interests, but prompts us to attempt to interrupt and supply facts and incidents he has left out of the pages. In reading the pages many front page stories of "the other day" are again brought to our attention.

We have not the space to attempt to give a resumé

BOOKS RECEIVED

Acknowledgment of all books received will be made in this column and this will be deemed by us a full equivalent to those sending them. A selection from this column will be made for review, as dictated by their merits, or in the interests of our readers

- MEDICAL GYMNASICS AND MASSAGE IN GENERAL PRACTICE.** By Dr J Arvedson Second edition. Translated and edited by Mina L Dobbie, M.D. 12mo of 284 pages Philadelphia, P Blakiston's Son and Company, 1926 Cloth, \$2 50
- GOULD'S MEDICAL DICTIONARY** Containing All the Words and Phrases Generally Used in Medicine and the Allied Sciences, With Their Proper Pronunciation, Derivation, and Definition By George M. Gould, A.M., M.D. Edited by R. J. E. Scott, M.D. Octavo of 1,398 pages, with illustrations and tables Philadelphia, P Blakiston's Son and Company, 1926 Flexible leather, \$9 00
- A MANUAL OF PROCTOLOGY** By T Chittenden Hill, Ph.B., M.D. Second edition, thoroughly revised 12mo of 294 pages, with 101 illustrations Philadelphia and New York, Lea and Febiger, 1926 Cloth, \$3 50
- A LABORATORY MANUAL FOR ELEMENTARY ZOOLOGY** By Libbie Henrietta Hyman (Second Edition) Octavo of 182 pages Chicago, Illinois, The University Press, 1926 Cloth, \$2 50
- A GUIDE FOR DIABETICS** By Walter R. Campbell, M.A., M.D., and Mame T Porter, B.Sc. Octavo of 259 pages Baltimore, The Williams & Wilkins Company, 1926 Cloth, \$2.50
- ESSAYS IN THE HISTORY OF MEDICINE.** By Karl Sudhoff, M.D. Translated by various hands and edited, with foreword and biographical sketch, by Fielding H Garrison, M.D. Octavo of 397 pages New York, Medical Life Press, 1926 Cloth, \$5 00
- THE ESCAPE FROM THE PRIMITIVE.** By Horace Carncross, M.D. Octavo of 348 pages New York and London, Charles Scribner's Sons, 1926 Cloth, \$2 50
- PRACTICAL DIETETICS FOR ADULTS AND CHILDREN IN HEALTH AND DISEASE.** By Sanford Blum, A.B., M.S., M.D. Second revised edition Octavo of 362 pages Philadelphia, F. A. Davis Company, 1926 Cloth, \$4 00
- DEFECTIVE MEMORY, ABSENTMINDEDNESS AND THEIR TREATMENT** By Arnold Lorand, M.D. Octavo of 340 pages Philadelphia, F. A. Davis Company 1926 Cloth, \$3 00
- A PRACTICE OF PHYSIOTHERAPY** By C. M. Sampson, M.D. Octavo of 620 pages, with 146 illustrations St. Louis, The C. V. Mosby Company, 1926 Cloth, \$10 00
- THE SURGICAL TREATMENT OF GOITRE** By Willard Bartlett, A.B., A.M., M.D. Octavo of 365 pages, with 130 illustrations St. Louis, The C. V. Mosby Company, 1926 Cloth, \$8.50
- OUR MINDS AND THEIR BODIES** By John Laird. 12mo of 122 pages London and New York, Oxford University Press, 1925 Cloth, \$1 00
- A TEXTBOOK OF THE PRACTICE OF MEDICINE.** By various authors Edited by Frederick W. Price, M.D. Second edition Octavo of 1828 pages London and New York, Oxford University Press, 1926 Cloth, \$10 00 (Oxford Medical Publications)
- I BELIEVE IN GOD AND IN EVOLUTION** By William W. Keen, M.D. Fourth Revised Edition, 12mo of 109 pages, illustrated Philadelphia and London, J. B. Lippincott Company, (1925) Cloth, \$1 25
- A MANUAL OF THE PARASITIC PROTOZOA OF MAN** By Charles F. Craig, M.D., M.A. Octavo of 569 pages, illustrated Philadelphia and London, J. B. Lippincott Company, 1926
- MEDICAL CLINICS OF NORTH AMERICA.** Vol 10, No 2 September, 1926. (Philadelphia Number) Published every other month by the W. B. Saunders Company, Philadelphia and London. Per Clinic Year (6 issues) Cloth, \$16 00 net, paper, \$12 00
- PLASTIC SURGERY OF THE HEAD, FACE AND NECK.** By H. Lyons Hunt, M.D., L.R.C.S. Octavo of 404 pages, illustrated with 342 engravings and 10 colored plates Philadelphia and New York, Lea and Febiger, 1926. Cloth, \$7 00
- WHAT'S BEST TO EAT?** By S. Henning Belfrage, M.D., M.R.C.S., L.R.C.P. With a Practical Supplement by Lucy H. Yates, M.C.A. Octavo of 199 pages. New York, William Wood and Company, 1926. Cloth, \$3 00
- THE INFLAMMATORY AND TOXIC DISEASES OF BONE.** A Text-Book for Senior Students By R. Lawford Knaggs, M.C., F.R.C.S., with numerous photomicrographs by C. H. Rodman, M.D. Octavo of 416 pages, 197 illustrations New York, William Wood and Company, 1926 Cloth, \$5 50
- FRESHMAN HYGIENE.** Personal and Social Problems of the College Student. By Raymond C. Bull, A.B., M.D., and Stanley Thomas, M.S., M.A. Octavo of 288 pages with 74 illustrations Philadelphia & London, J. B. Lippincott Company, 1926 Cloth, \$2 00
- RHEUMATISM, Its Meaning and Its Menace.** By Lewellys F. Barker, M.D. and Norman B. Cole, M.D. 12mo of 165 pages New York, London, D. Appleton and Company, 1926 Cloth, \$1 50
- METHODS AND PROBLEMS OF MEDICAL EDUCATION** Fifth Series Division of Medical Education, The Rockefeller Foundation, New York City, 1926 Quarto of 225 pages
- A PRACTICAL MEDICAL DICTIONARY** By Thomas Lathrop Stedman, A.M., M.D. Ninth Edition. Octavo of 1178 pages, illustrated. New York, William Wood and Company, 1926. Flexible leather, \$7 50
- WERK UND WIRKUNG—Eine Vortragsreise.** Von Professor Dr. Hans Much. 12mo of 227 pages, illustrated Leipzig, Curt Kabitzsch, 1926. Paper, Marks 7.20. (Moderne Biologie, Heft 11)

INTRAPERITONEAL TRANSFUSION IN VON JAKSCH'S ANEMIA *

By CLIFFORD G GRULEE, M D, Chicago, Illinois

INTRODUCTION

THERE has been a great deal of discussion as to whether *anemia pseudoleukemica* infantum of von Jaksch's is a clinical entity. It is not the purpose of this paper to attempt to decide this either one way or the other. All who have dealt with disease in children have seen cases of severe anemia accompanied by splenic enlargement in which there was an increase in white cells, the majority of which were of the mononuclear type. In these same cases there was likewise some enlargement of the liver, and, during the course of the affection, we encountered nucleated red cells, usually in abundance. The condition has no analog in later life, and apparently, both from the clinical and pathologic standpoints, shows great difference from any of the recognized blood diseases of adults. In connection with the splenic enlargement, I might offer the suggestion that lighter forms of the disease, as manifested in the blood examination, might be accompanied by enlargement of the spleen of a degree not so marked as we are accustomed to associate with this type of anemia. Again, in considering the same subject, the question of the etiologic importance of rickets in respect to splenic enlargement is one which perhaps may be of some moment in this connection. If I may state my own position in this matter, I will say that in my experience a spleen sufficiently enlarged to be palpable has never been considered to be a manifestation of rickets alone. Nor have I seen any proof that rickets may cause enlargement of the spleen, though this has been repeated in almost all treatises on the subject. Again in respect to rickets, one must bear in mind that a very large proportion of infants have rickets, and to ascribe to rickets an etiologic significance with respect to this type of anemia is, I think, assuming a

great deal in view of the fact that we have no pathologic or experimental proof. Cases of this type occur long after the active stage of rickets has passed, and while their origins are insidious, one can hardly stretch the imagination to the point of thinking that a child five or six years old with a typical history and findings of a von Jaksch's anemia, whose symptoms date back only a few months, has this condition as the result of a rickets whose active stage has passed by the time the child is two years old. The presence, therefore, in the following cases of rickets and splenic enlargement, combined with severe anemia, has been interpreted on the basis of a von Jaksch's anemia and not explained on the basis of rickets.

CASE REPORTS

The following cases of von Jaksch's anemia have all received intraperitoneal injections of citrated blood in greater or smaller quantities. The technic employed was as follows:

Two methods are used for intraperitoneal blood transfusion, one direct the other indirect.

Using the direct method, blood is drawn from the donor into a 100 c c glass syringe, and injected immediately into the peritoneal cavity of the recipient. If more than 100 c c is to be given, two syringes are used. By interchanging the two only one veni-puncture and one peritoneal puncture are necessary.

Using the indirect method, the blood is drawn from the donor into a "bleeding bottle." A 500 c c glass bottle is used. Two glass tubes fit into the stopper tightly. These are bent at an angle of 45° outside of the bottle. To one glass tube a short length of rubber tubing is attached (4-5 cm). A large 14 gauge needle is fitted into this rubber tubing. This allows movement of the bottle without dislodging the needle from the vein of the donor when shaking in order to mix the citrate solution with the blood. The second glass tube extends into the bottle a shorter distance than the

* Read at the Annual Meeting of the Medical Society of the State of New York at New York March 30, 1926

of the contents of the book. It deals with such varied topics as some words not in the dictionary, the German Kaiser in 1900, Hanna did not want Roosevelt, Bryan's great speech, The World's Fair, Mr Dooley, American Plays, The Klondike, Dewey sails for the Orient, Fashions in dress, Tools on the farm, Major Gorgas, Goethals takes charge, The automobile emerges, The Boxer movement, Assassination of McKinley, the Panama Republic Formed. These are but a handful of subjects found between the covers

Mark Sullivan needs no introduction to American readers. His name as the author of a work guarantees it to be instructive and interesting. What more can one ask of an author of a book? T S W

AIDS TO PHYSIOLOGY By JOHN TAIT, M.D., D.Sc., late Lecturer in Experimental Physiology, Edinburgh University, and R. A. KRAUSE, M.D., D.Sc. Second Edition. William Wood and Co., New York, 1924. Price, \$1.50

A little resumé of general physiology written, says the author in his preface, as an aid to the student who is presenting himself for examination and who has already attended lectures and practical courses. The volume is all that can be expected of a quiz compend. The type is poor and the illustrations necessarily abbreviated. FRANK E. MALLON

THE DEGENERATIVE DISEASES Their Causes and Prevention. By LEWELLYS F. BARKER, M.D., and THOMAS P. SPRUNT, M.D. Octavo of 254 pages. New York and London, Harper and Brothers, 1925. Cloth, \$4.00 (Harper's Public Health Series)

This is, indeed, a book of preventative medicine. It points out how to prolong the onset of the "diseases of old age," hence life by taking up the subject from the very beginning.

The much discussed, but hardly practical idea of doing away with the mental and bodily defective humans is discussed with the intention of breeding from higher stock. Next is considered the relation of environment to health and disease. Also the effect of eugenics and eugenics. Poisons, endogenous and exogenous, are also blamed for bringing on the degenerative diseases sooner than they should come on.

After the subject is discussed in a general way degeneration of the special systems is taken up. These include the arteries, heart, kidneys, digestive apparatus, nervous system, and the endocrine system.

It makes a very commendable addition to Harper's Public Health Series. KENNETH MAC INNES

NERVOUS AND MENTAL DISORDERS FROM BIRTH THROUGH ADOLESCENCE. By B. SACHS, M.D., and LOUIS HAUSMAN, M.D. Octavo of 861 pages, with illustrations. New York, Paul B. Hoeber, Inc., 1926. Cloth, \$10.00

More than eight hundred pages of freely readable material are contained in this excellent treatise on the diseases of the nervous system, and emphasis is directed to their association with childhood. It is not a revision of Dr. Sachs' former book on the Nervous Diseases of Children, he states in the preface "This is a new book."

The organic diseases are discussed in a comprehensive and exhaustive fashion, and the various syndromes of the extra pyramidal system are thoroughly reviewed.

Excellent chapters on anatomy, and methods of examination are of inestimable value to those less familiar with neurologic conditions.

A chapter by Dr. Sachs on the 'Normal Child, the Normal Youth,' with some of his personal views and criticisms regarding Freudian doctrines and psycho-

analysis, will prove very interesting reading to many, and a resumé of the functional nervous disorders round out a text book worthy of a place in every library.

A. M. RABINER.

AN INTRODUCTION TO THE STUDY OF X-RAYS AND RADIUM By HECTOR A. COLWELL, M.B. (Lond.), D.P.H. (Oxf.) and CECIL P. G. WAKELEY, F.R.C.S. (Eng.), F.R.S. (Edin.) Octavo of 203 pages, with illustrations. New York, Oxford University Press, 1926. Cloth, \$3.35 (Oxford Medical Publications)

This volume admirably serves its purpose as "An introduction to the study of X-rays and Radium." In very pleasing style the physics of these agents as known from the time of discovery to the present is described. The Atomic and Periodic laws are simply put forth and the relation to radium and X-ray noted.

The description of the preparation of Radium from mine to finished product of element and gas is most interesting.

The biological effects of radiation are briefly described, as is the use of the X-ray for diagnostic purposes.

A noteworthy chapter is that which deals with the protective measures to be observed in this specialty and concludes with the very important report of the Protection Committee of the National Physical Laboratory.

Even the appendix contains information of distinct value rarely found so compiled under one cover—it includes the definitions of fundamental and derived units, notes on index notation, table of development of the osseous system and finally notes on anatomical landmarks.

In brief we have at hand a volume of exceptional worth—not only to the beginner but to the most seasoned veteran in the field of Radiation therapy and Roentgen diagnosis. Further, it is of distinct general interest from the historical standpoint of the discovery and advances of the X-ray and Radium.

R. A. RENDICH

FUNDAMENTALS OF DERMATOLOGY By ALFRED SCHALEK, M.D. 12mo of 239 pages, with illustrations. Philadelphia and New York, Lea and Febiger, 1926. Cloth, \$3.00

The author attempts to furnish in accessible form such information as is essential for medical students and general practitioners. The various skin diseases are taken up very briefly in alphabetical order. The illustrations are well chosen and include several familiar faces.

The article on Creeping Eruption does not conform to the recent findings of Kirby-Smith.

The reviewer does not agree with the statements in regard to arsenic being a rare cause of dermatitis medicamentosa, nor in regard to its use in atrophy of the nails. In scleroderma arsenic has been found to frequently be the probable cause. Its use here would be positively contraindicated.

The little book however, will prove even more valuable to students than the old compend by the same author. It will be a boon to those wishing a hurried review before examinations, and to others who may be bewildered as they attempt to assimilate the enormous amount of material in the average full-sized text. Dr. Schalek has sifted this material so thoroughly that in some places little is left except an outline. On the whole the fundamentals are there, and that is all that a student can be expected to master in the few hours allotted to this important branch of medicine in the average curriculum.

Two pages of "Dermatological Aphorisms" are an unique and highly commendable feature of this book.

BINFORD THRONE.

living and well, two other children well

On examination the child showed large, but not very red tonsils. There was evidence of a fairly advanced rickets. The spleen was palpable—two fingers breadth below the costal margin. It is also noted that the right ear was discharging and the left drum was perforated. The electric irritability was slightly reduced. Liver dullness was three fingers below the costal margin. A roentgenogram showed some increased density in the hilus region. This child weighed 12 pounds, 1 ounce on entrance, and the weight curve was entirely unsatisfactory at the end of a month, the weight being exactly the same as at the time of entrance. The temperature of 101° F rapidly dropped and was not over 99.6° F thereafter, except for a slight rise on the 19th of the month, which dropped immediately to normal. She was given 100 c.c. of citrated blood on the 16th of March with no apparent local or general reaction. The urine was negative.

The child returned to the hospital on October 7, 1924, because of failure to talk and fits of temper. She was very evidently deficient mentally. At this time her Wassermann reaction was negative both in the blood and cerebrospinal fluid.

for several months. Three to four clay colored stools daily. He was Mexican by birth, delivered by a midwife, and, so far as could be ascertained, had no abnormalities during his newly born period. He suffered from some skin infection. The history was very unsatisfactory because of failure to obtain a good interpreter. On physical examination he showed definite signs of rickets. The general condition, however, was good, and he was quite fat and apparently well nourished. Pallor was not very noticeable. The axillary, cervical and inguinal glands were palpable—small and hard. The spleen was distinctly enlarged, almost to the umbilicus, and the liver was slightly enlarged. Pirquet was negative.

Upon entrance the child weighed 19 pounds, 4 ounces, and had an irregular weight curve. He left the hospital on November 20 weighing 20 pounds, 4 ounces.

His temperature was slightly up during his entire stay in the hospital, but never reached 101° F except on November 12, when it went to 101.6° F. It was usually between 99° and 100° F.

The urine was negative. The Wassermann reaction on October 10 was negative. This repeated on October 15 was again negative. This

Case III No 171,342, Salvadore J., 18 months. Entered Presbyterian Hospital October 9, 1923.

The complaint was that he had had diarrhea

child was given 60 c.c. of citrated blood intrapertoneally on November 1, and 90 c.c. on November 12. It is to be noted that the highest temperature which the child had was imme-

bleeding tube. A rubber tube and mouthpiece such as used on a blood pipet is attached to the second glass tube, and a wad of sterile cotton is placed in the glass tube itself. The operator sucks on this second tube while drawing the blood, thus producing a negative pressure in the bottle and facilitating the flow of blood into the bottle.

We use 10 cc of a 2½ per cent sodium citrate solution to each 100 cc of blood. The bottle is shaken gently while withdrawing the blood in order to mix the blood and citrate solution and prevent clotting.

After the required amount of blood has been withdrawn, the stopper is removed from the bottle, the neck of the bottle flamed and the blood strained through two thicknesses of gauze into the administrative apparatus. This consists of a container similar to that used in administering salvarsan by gravity method. It usually has a capacity of about 300 cc. To it is attached a rubber tube about 30 cm in length with a glass window and a glass needle tip.

The tubing is first filled with normal salt solution and all air expelled in this manner. This, of course, is more important if the blood is to be given intravenously. This precaution also lessens the chance of any clotting occurring in the tube before the flow begins.

The container is wrapped in hot towels to prevent cooling.

Blood is allowed to flow at the rate of about 30 cc a minute.

(breach delivery). He was immediately put on condensed milk, but did not develop properly. One month before entrance he had measles, which was followed by broncho-pneumonia. Two or three days before entrance he had a slight diarrhea. Family history was negative.

The only significant things about the child upon physical examination were a very large head, a large spleen and liver and the pallor which was quite noticeable during his stay in the hospital. His weight curve was extremely irregular and unsatisfactory. During the first two days, he had a temperature running as high as 102°-104° F. He had several rises of temperature from an acute naso-pharyngeal infection from time to time, but these had entirely disappeared by the 6th of March. On the 16th of that month there was a rapid rise and fall—the peak being 102°-104° F, following an intraperitoneal transfusion of blood.

The child left the hospital on the 5th of April. On February 27 the Wassermann reaction was negative. On the 28th some slight enlargement of the peribronchial glands was noted, but the Pirquet was negative on the 2nd of March.

Case II. No 164,651, Myrtle Z., 14 months. Entered Presbyterian Hospital March 1, 1923.

The complaint was loss of weight and vomiting. The child gained fairly well until the time she was one year old. The highest weight had been 13½ pounds. Vomiting began two

gain of a pound in six weeks. The temperature was below 100° F except on the 11th of February, when it rose to 101° F and dropped immediately. Thereafter, it was normal, or but slightly above normal until March 9, when it rose to 100° F, and showed a tendency to reach that height for ten days. Thereafter, the temperature remained below 99.6° F. On February 24 this child was given 38 c.c. of citrated blood serum intraperitoneally. On March 2, 25 c.c. of whole blood was given, and again on March 9, 58 c.c. was given. On March 15, 70 c.c. more was given. The urine was negative throughout. The Wassermann reaction on February 11 was negative.

four weeks later weighing 17 pounds, 6 ounces. The temperature from the original infection lasted for about ten days, following which there was no rise in temperature at all. The child left the hospital much improved.

Case VII No 177,121, Emanuel A., Age 2½ years. Entered Presbyterian Hospital April 22, 1924.

This child came in because of weakness of the lower limbs, and the mother said that he could not walk or stand. The child was a full term baby—the oldest of twins, and weighed at birth 8 pounds. He was breast fed for two months, and after that artificially fed. From

Case VI No 175,936, Zouart H., 15 months. Entered the Hospital March 13, 1924.

The child had been in the Durand Hospital—a diphtheria suspect. She was a twin, the other twin being in the hospital at the same time with lobar pneumonia and severe anemia. She was a seven months premature baby. On physical examination the child showed rather marked signs of rickets and a few rales in the chest. There was a slight systolic murmur heard at the base of the heart and transmitted. The liver was two fingers breadth below the costal margin and the spleen one finger breadth. The child was suffering from an acute nasopharyngitis with some bronchitis and severe anemia. The weight curve was very unsatisfactory. The child came in weighing 17 pounds, 14 ounces, and left the hospital almost

the history, he had evidently had a severe form of rickets before the end of the first year. Aside from an otitis media, the child had had no illnesses. On entrance he was pale, and showed definite remains of rachitic change. The epitrochlear glands were palpable. The heart showed a systolic murmur at the apex. The spleen was palpable, and the liver was three fingers breadth below the costal margin. The reflexes were normal.

The child had a temperature of 100.6° F on entrance, and it remained up throughout his stay in the hospital. On the fourth day it was as high as 102.6° F, but at the end of the week it had become almost normal. There was a sharp rise thereafter. This second rise was very evidently the result of an acute sore throat, noticed on April 29 when the tempera-

diately following the second transfusion The child returned to the hospital on January 13, 1925, having been sent in for diagnosis The complaint was that there was some hemorrhage in the soft tissue about the eye two weeks previously The child was constipated, cried when the bowels moved, and had frequent urinations and bed wetting On physical examination he was found to be well nourished and of good color The eye showed no effect from the hemorrhage The liver was $2\frac{1}{2}$ cm below the costal margin, and the spleen was just palpable Nothing else was found except the healed rickets

Case IV No 172,698, Keene P, 11 months Entered Presbyterian Hospital November 20, 1923

The child came in because of cough, rash about the buttocks, paler and rapid breathing He had been well until an attack of diarrhea the previous summer, after which he made a very poor recovery His cough was intermittently present He vomited often when fed He had no teeth, and had a red mottled rash about the buttocks He was a full term baby—breach delivery—and weighed 7 pounds, being one of twins The other child weighed 10 pounds at birth Some difficulty was encountered in resuscitating him He was cyanotic, but had no convulsions He had been breast fed for three weeks and then fed on milk mixtures The family history was negative except for the fact that the mother had had a miscarriage of twins of four months before any of her children had been born She had five other children living and three dead, one of diphtheria, one of pneumonia and one following a mastoid infection No venereal history was obtainable

Upon physical examination this child was noted to be remarkably pale All the super-

had not disappeared, but the heart murmur was no longer to be heard This child entered the hospital weighing 13 pounds, 1 ounce, and left in just a little over a month weighing 14 pounds, 15 ounces The temperature during the first week only at one time rose to 101° F It was almost continuously below 100° F On the afternoon of December 2 the temperature rose to 101.8° F, but immediately dropped to normal next day It did not rise to 100° F again until December 9, when it rose to 101.2° F, and dropped immediately There was another rise to the same height on December 16

On December 2 the child was given 50 cc of citrated blood, which corresponds to the second rise of temperature and the highest On December 9, 100 cc was given, and on December 16, 100 cc more Aside from the rise in temperature on the 9th, the child vomited following the transfusions, otherwise, there was no disturbance in the child's general condition The Wassermann reaction on November 21 was negative, on the blood, as was that on the cerebrospinal fluid Another test on the blood November 30 was again negative The roentgenographic findings confirmed the clinical diagnosis of unresolved pneumonia The child returned to the hospital on December 22, 1924, with broncho-pneumonia (secondary to whooping cough) and impetigo At this time his spleen was still palpable, and the liver was palpable two fingers below the costal margin He ran a stormy course and died December 24 No autopsy was obtained

Case V No 174,853, Lorraine A, 6 months Entered Presbyterian Hospital, November 6, 1924

She came in because of undernourishment, constipation and sweating at night The baby was premature, born at seven months, weigh-

ture rose. On the day following this acute rise in temperature from sore throat, the child was given 20 c.c. of blood intraperitoneally. The general condition thereafter was a little better. The tonsils remained red, however, and on May 2 the cervical glands became large and the condition gradually got worse. On May 4 it was noticed that the abdomen was somewhat distended, and the diagnosis of general peritonitis was made. It was not deemed advisable to operate at the time, and the child died May 6.

The Wassermann reaction on April 23 was negative, likewise on April 28. The urine was negative throughout. The autopsy findings were as follows:

"Anatomic diagnosis. Acute generalized serofibrinous peritonitis, hyperplasia of the mesenteric, mesocolic, tracheo-bronchial and

cause of discharging ears and pallor. The pallor, however, had been present since early infancy, but the mother thought the child was well except for the discharging ear. The child was full term, normal delivery, weighing 5 pounds. He had been breast fed for three weeks, and then fed on milk mixtures. Upon examination a very pale child was found and there was a discharge from the left ear. The pharynx was slightly reddened and the tonsils were enlarged. The liver was two fingers breadth below the costal margin, and the spleen was palpable. The child had a very poor weight curve while in the hospital, but lost no weight.

His temperature throughout his stay was normal except that, on the second and third days after entrance, it was respectively 100.2°

CASE VIII No 177,446, SAM F, 17 MONTHS

cervical lymph glands, hyperplasia of the spleen, hyperplasia of the Peyer's patches, acute bilateral fibrinous pleuritis, cloudy swelling of the myocardium, fatty changes of the liver, gas-distended small bowel, healed needle puncture wound of the abdomen, generalized icterus, acute emaciation, acute generalized anemia, prominent parietal eminences."

It may be noted that there were no signs of inflammation about the needle wound from the transfusion of blood and that the peritonitis came on only five days after the transfusion and there was accompanying fibrinous pleuritis. The danger of giving intraperitoneal transfusion of blood was recognized, but it was thought that the risk must be taken if the child were to be given any chance at all.

Case VIII No 177,446, Sam F, 17 months. Entered Presbyterian Hospital May 3, 1924.

This child was brought to the hospital be-

cause of discharging ears and pallor. The pallor, however, had been present since early infancy, but the mother thought the child was well except for the discharging ear. The child was full term, normal delivery, weighing 5 pounds. He had been breast fed for three weeks, and then fed on milk mixtures. Upon examination a very pale child was found and there was a discharge from the left ear. The pharynx was slightly reddened and the tonsils were enlarged. The liver was two fingers breadth below the costal margin, and the spleen was palpable. The child had a very poor weight curve while in the hospital, but lost no weight.

His temperature throughout his stay was normal except that, on the second and third days after entrance, it was respectively 100.2° F and 100.6° F. This child was given a transfusion of 25 c.c. of blood on May 9. The urine was negative. The Wassermann reaction was negative. He left the hospital on May 18 improved.

He returned to the hospital June 14 because of pallor, poor appetite and general weakness. At that time the physical findings were essentially the same as previously. On June 26 he developed a discharge from his left ear. The temperature was essentially the same as on his previous entrance. During his second stay in the hospital, he received 20 c.c. of blood intraperitoneally on June 20. The urine was negative. He left the hospital improved on July 10.

Case IX No 183,739, Elaine G, 3 years. Entered Presbyterian Hospital November 21, 1924.

This child came because of anemia, loss of weight and of appetite. On October 16, the

exception fever was present the whole time and from December 15 until his death reached 105° F, or near it each day

The Wassermann reaction was negative on four different occasions, and the urine at no time showed anything abnormal. No parasites were present in the stools and no blood was found in them

Autopsy was refused

Case XII No 196,192, Louise K, 9 months Entered Presbyterian Hospital January 18, 1926

This child came in because of a bad cough and weakness with loss of weight. She had had pneumonia the previous September which had lasted for two or three weeks. By the middle of November she had recovered, but she began to cough again. The child had never been breast fed. The family history was negative. On physical examination this child seemed to be quite pale and there were signs of bronchitis and some rickets, though this was not marked. The liver was slightly enlarged and the spleen was hard and easily palpable. Other than this no findings were present. The child came in with a slight fever which continued throughout her illness. She had occasional attacks of acute nasopharyngitis. Aside from this her course in the hospital was uneventful except for slight epistaxis on two mornings just

before she left the hospital. Her blood chemistry was normal.

The Wassermann reaction was negative on four occasions and the spinal fluid on one occasion. She received blood intraperitoneally—165 c.c. in one transfusion, and left the hospital in good condition on March 11.

These cases varied in age between six months and three years. Of those cases under one year, two (Cases V and XII) recovered and one (Case III) died of broncho-pneumonia after a decided improvement in the blood. Of the five cases over one year and less than two years, two (Cases II and III) recovered, two (Cases VI and VIII) left the hospital improved and one (Case I) showed no change. Four patients of two years or over died. This has been the most striking feature in the study of these children, and very likely has some very definite significance.

The results of intraperitoneal transfusion may be considered from two standpoints, the immediate and the ultimate. The immediate results in almost all cases were good. This is not shown alone by the effect upon the blood picture. Within a week's time there was usually a distinct improvement not only in the red cells and hemoglobin, but also in the white cells. The effect on the general condition of the patient was, if anything, more striking than

suffering Since August 29 she had been listless and had lost weight, and she had become pale The parents noted that there was a swelling in the abdomen There was burning on urination The history otherwise was negative On examination the child seemed to be extremely pale The cervical, axillary, epitrochlear and inguinal glands were palpable The left border of the heart was about 2 cm to the left of the nipple line There was a systolic murmur heard best at the apex The liver was felt about 6 cm below the costal margin, and the spleen about 4 cm below the level of the umbilicus There was marked improvement following the use of large quantities of blood intraperitoneally Not only did the anemia clear up, but the other symptoms rapidly improved Roentgenotherapy of the spleen was given at the same time

The child left the hospital on October 16 very markedly improved She returned on November 4 in practically the same state she was in previous to her first entrance, if not worse The spleen at this time was so large that it impinged on the pelvic rim, causing pressure on the stomach and consequent vomiting Roentgenotherapy of the spleen resulted in reduction of the size and relief from the vomiting On November 17, it was decided to do a splenectomy because other measures had proven of no value The splenectomy, however, failed to relieve the condition, and the child died on November 25 During her sec-

Only partial autopsy was allowed, and the anatomic diagnosis was Marked general anemia, myeloid metaplasia of the liver, ascites, multiple spontaneous hemorrhages of the skin

Case XI. No 193,882, Jerome S, 3 years
Entered Presbyterian Hospital October 27, 1925, on the service of Dr Bevan

He came in because of a pallor which had been present for five months and pain in the abdomen This pallor had been noted since the preceding July and there had also been an indefinite pain in the abdomen at that time and since There was some vomiting, but no loss of weight Aside from this there was nothing of interest in the history The examination revealed an exceedingly pale boy, large tonsils, a very rapid heart, over which there was a loud systolic blow well transmitted The liver was 7 cm below the costal margin and the spleen 6 cm There was some enlargement of the inguinal glands also of the cervical and axillary glands The left epitrochlear was palpable

This child was given a number of intraperitoneal transfusions of blood which resulted in a marked betterment, so that by December 3 the hemoglobin, which had been at 11 per cent, had reached 80 Thereafter there was a very marked and rapid decline, and the child died on December 23 Throughout his course in the hospital he had an irregular fever often running to 100° F-103° F or 104° F There was a period from November 12 until November 24 when this was not true, but with this

the one which interests us in this paper The interacinar pancreatitis is the result of arteriosclerosis and is usually associated with diabetes This bears little, if any, relation to infection The pathological process is confined to the lobules with destruction of the acini and the islands of Langerhans Chronic interlobular pancreatitis does not involve the lobules

Histology—The histological picture, as shown in Figure 1, is that of a tubo-alveolar gland with lobules connected by the interlobular connective tissue. The acini are in definite lobules, and the interlobular tissue contains the blood vessels, ducts, and lymphatics The islands of Langerhans are in the central portion of the lobules

Lymphatics—The lymph drainage to the pancreas is not general but is confined to definite areas Figure 2, from the work of Bartels (2) shows the body and tail of the pancreas receiving lymph, chiefly from the left side of the abdomen From this illustration we see the head of the gland is not affected to any great extent The work of Franke (6) as illustrated in Figures 3 and 4, reveal direct lymph drainage from the gall-bladder to the head of the pancreas This is confined to the area of pancreatic inflammation between the duodenum and the converging ducts of Santorini and Wirsung The work of Braithwaite (3) in Figure 5, shows

Fig 1 Section of pancreas showing interlobular tissue with vessels, nerve, and duct and surrounding tubular alveoli.

the glands injected in the iliocecal region with retrograde drainage to the pancreatoduodenal lymph nodes in the region of the head of the pancreas The pancreatoduodenal lymph nodes are connected with those along the common duct and portal vein From the above data it would seem that the head of the pancreas is

Fig 2

chiefly involved in infection of the right side of the abdomen, whether it be cholecystitis, appendicitis or ulcers of the stomach or duodenum

Etiology of Chronic Pancreatitis—It seems that chronic interstitial pancreatitis is the result of lymphatic infection from some other primary abdominal focus Deaver and Pfeiffer (4) report a series of fifty-two cases of chronic pancreatitis in which the head alone was affected in forty-two In only nine was the tail involved In twenty-seven cases there was well marked evidence of involvement of the lymph nodes in the neighborhood of the head of the pancreas They found the infection localized chiefly in the triangle of the pancreatic infection, between the duodenum and converging ducts of Santorini and Wirsung They attribute the chronic infection to lymphatic origin If the infection ascends the pancreatic ducts, the induration should be more general The lymphatics from the gall-bladder drain only to the triangle of pancreatic inflammation, as has been demonstrated by Franke. Deaver reported seventy-nine patients with chronic pancreatitis at the Lankenau Hospital, seventy-two or ninety-one per cent showed evidence of biliary infection, forty-two or fifty-three per cent had calculi, while thirty or thirty-eight per cent showed a non-coliculous inflammation W J Mayo (13) reports that ninety per cent of the cases having acute and chronic pancreatitis have been operated upon for infected

that on the blood picture. While in many instances there was a sharp rise of temperature within a few hours after the transfusion, this usually subsided and was followed within twenty-four hours by a very definite change in the clinical picture. These children who had previously been much fatigued by the slightest effort, were very apathic and peevish, with poor appetite and no response to surroundings, would often become cheerful, alert, and show a much increased desire for food. In the one case where death followed from acute fibrinous peritonitis the first symptoms of this appeared five days after the introduction of blood in a child who was suffering from a severe septic sore throat. Both the pathologist and I interpreted this as a metastatic peritonitis, but one cannot deny the possibility either that the blood so introduced had produced an area which was favorable for the cultivation of bacteria, or that some infection had been introduced at the time of the transfusion.

Of the ultimate results one cannot speak so positively. It is apparent that in the younger children in many instances the reaction to blood transfusion was all and more than could be expected. In some instances this was so marked as to suggest that the transfusion had very little to do with the child's recovery, but this was not usually the case, and it is possible that small quantities of blood may have so stimulated the blood forming organs as to have obtained the desired result without further transfusion. On the other hand, in the older

children large quantities of blood brought about very marked amelioration of the condition over several weeks time. The surprising fact is that there came a period when the child was apparently well on the road to recovery when neither intraperitoneal transfusion nor other therapeutic measures were of any value in preventing a marked and rapid decline to the point of death.

There is still to be considered the question of whether such transfusions had a deleterious effect upon the patient. This seems hardly to be the case. In those cases where blood transfusion was followed by a rapid improvement, and which ended rather catastrophically with death, no other measures tried seemed to have had any better effect. Not only is this true, but it is also true that in most instances these cases were undergoing a rapid decline before transfusion was attempted.

In conclusion, we may say that, judging from this series of cases, there seems to be an age element which is a determining factor in von Jaksch's anemia. The younger children, that is those under two years, do much better than do the older ones. Intraperitoneal transfusion gives the possibility of introducing large quantities of blood at short intervals without much difficulty. The results obtained show certainly that the immediate amelioration is fairly constant and often quite marked. The ultimate results, in older children especially, are not nearly so happy.

THE CLINICAL FEATURES OF CHRONIC PANCREATITIS*

By J WILLIAM HINTON, M D, New York, N Y

Associate in Surgery at New York Post-Graduate Medical School and Hospital Adjunct Assistant Visiting Surgeon, Bellevue Hospital

ATTENTION was first drawn to chronic pancreatitis as a clinical entity by Mayo-Robson in 1900 (11). At that time he thought the pancreatic lesion was the one of primary importance in a high percentage of chronic upper abdominal surgical conditions. He was of the opinion that a correct diagnosis could be made in the majority of cases of chronic pancreatitis before a laparotomy was performed. In this paper we are interested in the clinical features of chronic interstitial pancreatitis, which are exhibited after laparotomies have been performed for cholecystitis, ulcers of the stomach or duodenum, or appendicitis. Attention has recently been drawn to chronic pancreatitis as a

clinical entity, in this connection, in a paper which I published in *Surgery Gynecology and Obstetrics* (7). The symptoms of the associated lesion from which pancreatitis arises or with which it is associated, usually overshadow those of pancreatitis and make the primary diagnosis of the latter more or less speculative. After the primary lesion has been eliminated by surgical intervention, chronic pancreatitis should be diagnosed with a much higher degree of accuracy without submitting these patients to a second operation.

Chronic pancreatitis is divided into two forms. *First* Chronic interlobular pancreatitis. *Second* Chronic interacinar pancreatitis. The interlobular type results from bacterial infection of the connective tissue lying between the lobules, and is

* Read before the Annual Meeting of the Medical Society of the State of New York, at New York, March 31 1926

pancreatitis is usually confined to the head of the gland and from figure No 6 one will see the marked increase in the interlobular fibrous tissue and, to a smaller degree, in the interacinar tissue. The islands of Langerhans are not affected. The acini at the periphery of the lobules may atrophy. In view of the fact that the lymphatic drainage is confined to the interlobular tissue and to the head of the gland, one would expect to find this portion of the gland chiefly involved. The pathological data we have on this subject will be published at a later date

Signs and Symptoms of Chronic Pancreatitis
—The history, physical examination and laboratory findings are the most important aids in the diagnosis of this condition. The acute exacerbations of the chronic disease give one the lead on which he is to arrive at the diagnosis. Patients presenting themselves with a history of attacks of pain, similar to the ones they had before gall-bladder or stomach surgery, should be suspected of having chronic pancreatitis. *Pain*—This is

Fig 5 Diagram showing area of glands injected in the living subject from an ileocaecal gland puncture. (From Braithwaite.)

Fig 6. Section from a fibrosed pancreas showing a combination of centrilobular and perilobular types. There has been obstruction and dilatation of the main ducts, A, and their branches, B. The lobules are separated by broad perilobular bands of fibrous tissue and the individual acini, C, in the lobules are similarly separated by a centrilobular fibrosis (From Adam and McCrae.)

the chief complaint of the patient and the individual is usually seized with a severe upper abdominal pain which is constant in character. It is difficult for these patients to localize the pain. Occasionally they say it is in the right upper quadrant and radiates to the back. More frequently they state that the pain is on the left side in the region of the left kidney. Due to its location on the left side, it would make one suspect a renal calculus. The intensity of the pain will vary in different individuals, presumably depending upon the severity of the pancreatic involvement. These attacks may last from a few hours to forty-eight to seventy-two hours. If the pain is located in the left kidney region at the beginning of the attack, it quite frequently localizes itself in the upper abdomen in the middle of the epigastrium after forty-eight hours. The patient usually feels normal within a few hours after the pain subsides. The cause of the sudden attacks of pain is probably due to acute exacerbation of the chronic lymphangitis, which results in swelling and edema of the head of the gland, or it may be due to a chemical alteration in the secretion of the pancreas, which is normally alkaline. The infection may convert the trypsinogen into an activated trypsin with its proteolytic properties. *Nausea* is not commonly seen in this condition. *Vomiting* is usually en-

gall-bladder, usually with gall-stones Archibald in 1913, in a paper titled "A New Factor in the Causation of Pancreatitis" (1), reported thirty-six cases of pancreatitis in sixty per cent of which gall-stones were absent He attributes the pancreatitis to a spasm of the phincter of Oddi at the papilla, which results in bile entering the pancreatic ducts Mann and Giordano (10), working experimentally on goats, doubly ligated the common bile duct and divided it as its entrance into the duodenum The animals lived from one to thirty days In none was there either macroscopically or microscopically an area with the appearance of acute hemorrhagic pancreatitis The results of these experiments emphasize first, that with the pancreatic duct emptying directly into the common bile duct and the latter completely obstructed, bile was not forced into the pancreas except after a considerable length of time Second, that bile did pass

Fig 3

into the pancreatic duct and infiltrated the pancreas completely when under the maximum of pressure which the physiological mechanism of

Fig 4 The Darkened Area is the portion of the Pancreas involved in Chronic Pancreatitis It also represents the relation of the Pancreatic Ducts and Common Bile Ducts

- the animal could produce Acute hemorrhagic pancreatitis was not seen From the data on the relation of the duct of Wirsung to the common bile duct, which is shown in Table 1, it is anatomically possible for obstruction existing at the ampulla to convert the two ducts into a continuous channel and allow bile to pass in the pancreatic duct in 35 cases

Sweet (15), in working experimentally on dogs, has been able to remove a portion of the pancreas and join the head of the pancreas or the duct to the intestine without danger of pancreatitis, either acute or chronic, for as long as an eleven months' interval From this it would not seem that infection ascends by way of the duct

Eggers (5) gives two possible causes of acute pancreatitis first, that symptoms are due to infection or ferment action owing to the entrance of bile or duodenal contents into the pancreatic duct, second, that it is an infection carried to the pancreas by means of the lymphatics He leans to the theory that infection as such has nothing or little to do with acute pancreatitis, but that it is due to the action of the liberated pancreatic ferments on the surrounding tissues In six cases reported by him, five had gall-stones and the sixth had a cholecystitis

From the above data it would seem that the gall-bladder and biliary system are the primary factors in producing chronic infection of the pancreas Ulcers of the duodenum probably play the second most important role, while the appendix and iliocecal angle have a direct lymphatic drainage to the head of the pancreas

Pathology—The interlobular connective tissue is more susceptible to bacterial infection than the other pancreatic tissue Chronic interstitial

taneously subsides after removing the primary abdominal focus

THE TONSIL AND ADENOID PROBLEM IN NASSAU COUNTY*

By GERALD HUTCHINSON COX, M.D., F.A.C.S., Glen Cove, N. Y.

ONE of the problems confronting the Nassau County Tuberculosis and Public Health Committee, which furnishes nutrition and health workers to the public schools of the County, is the task of securing adequate hospital treatment for the large number of adenoid and tonsil cases annually requiring operation.

It seemed to the writer, a member of the committee, that a careful study of the adenoid and tonsil situation in the schools might yield results of considerable value.

The subject was first approached through figures furnished by the Department of Education at Albany, and secondly, by the examination of a series of school children by me personally.

The State Medical Inspection Law calls for one annual physical examination of each school child in the State, for school inspection whenever expedient, and for preventive care of all children suffering from disease or physical defect.

Dr. Howe and Dr. Mace, of the New York State Department of Education, kindly furnished me with the departmental statistics, which give 37,950 public school children in Nassau County during the year 1924-1925. Of these, 20,181 live in the rural districts. Of the 20,181 (rural district children) the Department of Education found 3,365 adenoid and tonsil cases needing treatment, equal to 11 1/5 per cent. The percentage requiring operation in the

cities such as Glen Cove and Long Beach is not at hand. Probably the proportion among the city children does not differ considerably from the rural children. According to the same source of information, of the 3,365 cases needing treatment, 808, or 24 per cent, were operated upon during the year. If we accept the official figure, we are confronted with a serious problem. Unfortunately, however, my own studies indicate that the percentage of adenoid and tonsil cases requiring treatment is materially larger than the figures of the Department of Education.

For the purpose of my survey, I decided to examine about 300 children in five schools situated in an imaginary line bisecting Nassau County. These schools are located at Oyster Bay, Locust Valley, Roslyn Heights, Mineola and North Belmore. In all, 309 were examined, of which 260 were chosen by class rooms picked at random because they were not engaged in recitations at the time of my visit.

I found that 53 3/4 per cent need operation, 13 1/2 per cent had already been operated (many of them in New York City before they moved to Long Island), 32 3/4 per cent do not require treatment.

In my work, the majority of the children were examined by artificial light, using head mirror, tongue depressor, post-nasal mirror and nasal speculum. Considerable care was taken in selecting the operative cases. The mere presence of a pair of slightly enlarged healthy tonsils in a child's throat was not con-

*Read before the Nassau County Medical Society, October 26, 1926.

schools examined, when physical defects are found, the children are requested to give cards to their parents which state that the child should be taken to his physician or to a clinic for diagnosis and treatment. The children often fail to turn these cards over to their parents. Even if there is a school nurse in attendance, many of these nurses are on part time and consequently unable to give the requisite amount of attention to the work.

The ignorance of parents as to the necessity for adenoid and tonsil operations is appalling. Some sort of educational campaign will be necessary to make parents realize the importance of having adenoid and tonsil defects removed.

We come now to the question of how the poor child, unable to pay for treatment, can secure the necessary hospital care. At the present time, we may say that practically the only institution in the County where free treatment can be obtained is the Nassau Hospital. A patient entering the ward is expected to pay \$8.00 for a bed in the ward and use of the operating room. If the patients are too poor to pay, the hospital fee is remitted in whole or in part after investigation by the social service worker. The method of procedure is as follows: a list of children needing operation is sent in by the school nurse. The next step is a visit to the child's home by the social service worker of the hospital. Many of these children live at considerable distances from the hospital and far apart. The number of ward beds is limited. Consequently there is often a long period between the time when the child's name is handed to the hospital authorities and the day when the case is actually admitted to the ward for operation.

PRE-OPERATIVE CARE OF PATIENTS

Every child, before being subjected to a tonsil and adenoid operation, should have a complete physical examination, including the heart, lungs, kidneys and coagulation time. The nose should be examined by artificial light and a nasal speculum should be used so that the child may not be operated upon for tonsils when he is suffering from some obstruction in the anterior nares. It is important to take the temperature and to postpone operation if it is over 100 degrees F. In examining each child, considerable care should be given not only to the indications for removing the tonsils and adenoid but also to his general condition and ability to stand the operation. Cardiac and nephritic cases, as well as markedly undernourished children, should be sent into the hospital several days before operation for observation.

It is not within the province of this paper to discuss the type of operation to be performed. It is essential that a complete removal of the tonsil be carried out in a thoroughly surgical manner and in as dry a field as it is possible to

produce with a good suction apparatus. The operation on children should always be done under a general anaesthetic, of which the safest is gas and ether or ether alone for very young children. Moore, of the Jackson Bronchoscopic Clinic, has called attention to the fact that the largest number of pulmonary abscesses found in any one section of the country come from the vicinity of eastern Massachusetts, where most patients are operated upon in a sitting or semi-recumbent position under general anaesthesia. Apparently the recumbent position, with the head slightly lowered, is less apt to be followed by aspiration of blood or bacteria and the production of a foreign body pneumonia or lung abscesses.

In some hospitals, notably the Tonsil Hospital of New York, patients are given calcium lactate three days before operation to prevent bleeding. The dosage is $7\frac{1}{2}$ grains three times a day for small children and 10 grains for older children.

It is now generally recognized that cases with status lymphaticus and an enlarged thymus gland take anaesthetics badly, especially chloroform. A hypertrophied thymus gland can usually be recognized by radiography, and the gland will rapidly diminish in size under X-ray treatment. Of course, in routine tonsil work, it is hardly possible to make radiographs of ward adenoid and tonsil cases, although all operators should bear this condition in mind.

An editorial in the *Journal of the American Medical Association* of April 17th, 1926, has called attention to the observations of Zingher, working in the New York City department of Health, on the association of diphtheria with tonsil operations. Zingher has found that diphtheria is apt to develop in a patient who has just been operated upon for adenoids and tonsils if the patient is susceptible, as shown by a positive Schick test and if he is a carrier of virulent diphtheria bacilli. The *Journal* points out that although "these three factors—absence of general immunity to diphtheria, presence of virulent diphtheria bacilli in the nose or throat, and an operation, such as tonsillectomy—may not come together frequently, yet Zingher believes that when they are present in the same person, diphtheria is quite certain to follow and the disease is likely to prove unusually dangerous. The serious nature of the superimposed diphtheria arises, Zingher adds, from the danger of an early and rapid absorption of a fatal dose of toxin from the extensive raw surface, and from the difficulty in recognizing the disease in the sloughing post-operative membrane until much valuable time has been lost and the opportunity for effective administration of antitoxin has slipped by."

Zingher recommends "that nose and throat cultures for diphtheria bacilli be taken as a routine before such operations as tonsillectomy and ade-

sidered an indication for operation. In the group requiring operative treatment were included the following:

Adenoids and hypertrophied tonsils, which by their size interfered with breathing and swallowing, diseased tonsils with pus or secretion in the crypts where the child's general health and nutrition obviously suffered, tonsils associated with attacks of sore throat, glands of the neck, ear ache or discharging ears, children who were backward mentally, behind in their grade or inattentive in their work when found to have diseased or enlarged tonsils and adenoids.

In New York City, working many years in the nose and throat department of the Manhattan Eye, Ear and Throat Hospital, it frequently fell to my lot to decline to operate upon patients referred by the school authorities, when it seemed to me to be unnecessary. In Nassau County, on the other hand, the school physicians are apparently confining their recommendations for operation to the most pronounced types of hypertrophy or disease.

There are approximately 15,000 pre-school children in Nassau County. It is probably fair to assume that at least 15 per cent of these need adenoid and tonsil operations. As stated above, there were 37,950 school children in the County during the year 1924-1925, of whom, if my investigation is correct, over 50 per cent need treatment. Adding the number of pre-school children needing operation to the number of school children requiring treatment, we find that there are probably at least 21,000 children in Nassau County today in need of treatment.

It is now generally recognized that the tonsil operation is essentially a hospital operation and that the patient should not be operated upon in the physician's office, in the clinic or at home.

WHAT HOSPITALS ARE AVAILABLE FOR TAKING CARE OF ADENOID AND TONSIL CASES?

- A Nassau Hospital
- B Glen Cove Community Hospital
- C Mercy Hospital in Hempstead
- D New York City Hospitals

A Nassau Hospital took care of 540 adenoid and tonsil cases during the year 1925, of which about 100 were private cases. Some of the private cases were adults.

B In the Glen Cove Hospital during 1925, 116 adenoid and tonsil cases were operated upon. A number of these patients were adults and all were private cases with the exception of a few children whom I operated upon with the help of Dr. Jackson, Dr. Derby's associate, and Dr. Maryland Burns, who is working on cases of malnutrition.

C At the Mercy Hospital, from July, 1925, to July, 1926, 10 adults and 105 children were

operated upon for adenoids and tonsils. The majority were private cases.

D Some of the New York City hospitals may be utilized to take care of the poor children in Nassau County who are unable to pay for operations, but many of the city hospitals are already overtaxed by the local cases.

Thus we see that during the past year, with some twenty odd thousand children in Nassau County needing operative treatment, not over 800 have had hospital operations in the County during that period. Doubtless a small number of children have been operated upon in the doctor's office or in the children's homes by private physicians, but I feel certain, from my knowledge of the physicians of the County, that this does not take place to any appreciable extent.

DEFECTS IN SYSTEM OF MEDICAL SUPERVISION

My visits to the schools, where I examined these children, showed that there are many defects in the school system of medical inspection. The State Medical Inspection Law, as stated above, calls for one annual physical examination of each school child in the State. The trustees of some of the schools are not carrying out the provisions of this law. In one large school in the County, the trustees have a contract which calls for the payment of 75 cents for each child examined by the school physician. As the trustees do not care to spend but a small sum of money on medical examination, they only permit the school physician to examine the pupils in the first and fifth grades, with the exception of a few pupils who are transferred from other schools during the year. In another school of approximately 500 children, the school doctor is paid \$125.00 per year for making a complete physical examination of each child, giving toxin anti-toxin treatment for prevention of diphtheria and for consultation if a case of infectious disease is suspected. In this particular school, it is obvious that the physician is very much underpaid, although he performs his duties in a conscientious fashion because of his interest in the health of the community.

One of the most glaring defects discovered by me in the schools which I visited, was the fact that there was no school nurse in one institution with approximately 600 pupils. In this school, the physician examined the pupils, wrote down the physical defects found on cards which were filed away and promptly forgotten. During the past winter, the Nassau County Tuberculosis Committee sent a nutrition worker to visit this school once a week. This young lady has endeavored to follow up the tonsil cases who were recommended for operation, but has met with little success on account of the limited time at her disposal.

The follow-up system for operative adenoid and tonsil cases is far from perfect. In all the

OUR NEW LOCATION

The Medical Society of the State of New York moved into its rooms in the new building of the New York Academy of Medicine on November eighth. The new location is at 2 East 103rd Street, at the southeast corner of that street and Fifth Avenue. It may be reached most easily by the Lexington Avenue Subway to One Hundred and Third Street.

The main rooms of the Society and those of the Secretary are on the fourth floor, and the telephone number of the Society is

ATWATER 7524

The New York State Journal of Medicine oc-

cupies rooms on the fifth floor, and its telephone number is

ATWATER 5056

The Editorial and Secretarial rooms are interconnected by telephone, and both are connected with the main switchboard of the Academy, whose number is

ATWATER 4700

The new rooms provide enlarged working space for the clerical staff and privacy for conferences of the officers, and are in keeping with the enlarged scope of activities of the State Society.

noidectomy If the cultures are positive, a prophylactic dose of diphtheria antitoxin should be administered In carriers who are to be treated by the removal of tonsils and adenoids, it is especially important to make certain that the patient either gives a negative Schick reaction, or, if a positive Schick reaction is obtained, that he receives a prophylactic dose of diphtheria antitoxin"

POST-OPERATIVE CARE OF PATIENTS

Each child should remain approximately 24 hours in the hospital after operation for observation and treatment If this is done, the danger of post-operative hemorrhage and post-operative pneumonia is considerably diminished I am glad to say that during the past twelve years a marked change for the better has taken place as to the need of post-operative hospital care for tonsil cases For example, in 1913, in a report made by me to the New York Academy of Medicine, it was found that of twenty-two hospitals and dispensaries questioned by the New York City Visiting Committee of the State Charities Aid Association, nine lived up to their obligations and kept their patients approximately 24 hours or longer for observation and treatment In four of the other institutions, the children were allowed to go home directly after operation In seven clinics they were kept from one hour to twenty-four hours, usually from one hour to three hours One well known clinic sent its patients home "as soon as sufficiently recovered from the anaesthetic," notwithstanding the fact that its operators always perform a total enucleation of the tonsils under chloroform or ether Two other clinics performed tonsilleotomies and allowed the children to go home two hours later This report awoke the school authorities, the New York City Department of Health and the Public Health Committee of the Academy of Medicine to the need of a radical change, which was promptly recommended Consequently, at the present time, practically all good hospitals keep their tonsil cases in the wards at least through the night following operation The principal offenders of today are private physicians who operate in their offices or in the homes of poor patients who live in crowded, unsanitary surroundings

Dr Lewinski-Corwin, writing for the Public Health Committee of the New York Academy of Medicine, in the *Medical Record*, May 14, 1921, has called attention to the fact that "the loss of weight following operation stands in inverse ratio to the number of days in bed after the operation and the regaining of weight is much more rapid in cases which have had a few days' rest"

Again, when I compared the post-operative cases seen in New York in 1913 with the post-operative cases observed in Nassau County during the present study, I was tremendously impressed with the great improvement which has

taken place in tonsil surgery during the past twelve years

For example, among the 309 school children examined in Nassau County, I found 37 who had already been operated upon, some in Nassau Hospital, some in Glen Cove, and others in New York City before moving to Long Island In only one of the 37 Nassau cases, did it seem necessary to advise re-operation Further, there were no mutilations of the soft parts Going back once more to my paper of 1913, I found that of 89 New York City children, who had been operated upon, 9, or approximately 10 per cent, received mutilations of the soft parts adjoining the tonsils Of 52 New York cases operated upon with general anaesthesia, 12, or 25 per cent were poorly done

While the number of operative cases (37) examined by me in Nassau County is too small for reliable data, yet the results observed certainly indicate that the tonsil operation had greatly improved during the past decade

SUMMARY

1 My studies indicate that there are today over 21,000 children in Nassau County who need treatment for adenoids and tonsils

2 During the past year less than 1,000 were treated in the hospitals of the County

RECOMMENDATIONS

1 More hospitals should be built in various centers throughout the County

2 Greater utilization should be made of the present hospital facilities

3 Adequate salaries should be paid school physicians to insure good work on the part of the doctors

4 Every public school should have a resident nurse in daily attendance, preferably on full time

5 After a child has been examined by the school physician and the defects noted on his card, a reliable follow-up system should be instituted so that the recommendations of the physician be carried out

6 All children, who can afford to pay, should be encouraged to have their adenoids and tonsils removed in the private or semi-private service of the hospital If this is done, there will be more ward beds available for the deserving poor who are unable to pay In order to make this possible, the rates for the semi-private patients should be as moderate as is consistent with the running expenses of the hospital

7 A publicity campaign to enlighten ignorant parents many of them foreigners, as to the necessity for adenoid and tonsil operations is essential This can be accomplished by the daily press, by talks to both children and parents at the schools, and by the distribution of pamphlets such as that furnished by the Metropolitan Life Insurance Company

EDITORIAL

NEW YORK STATE JOURNAL OF MEDICINE

Published by the Medical Society of the State of New York under the auspices of the Committee on Publication

Business and Editorial Office—2 East 103rd Street, New York, N.Y. Telephone, Atwater 5056

noidectomy. If the cultures are positive, a prophylactic dose of diphtheria antitoxin should be administered. In carriers who are to be treated by the removal of tonsils and adenoids, it is especially important to make certain that the patient either gives a negative Schick reaction, or, if a positive Schick reaction is obtained, that he receives a prophylactic dose of diphtheria antitoxin."

POST-OPERATIVE CARE OF PATIENTS

Each child should remain approximately 24 hours in the hospital after operation for observation and treatment. If this is done, the danger of post-operative hemorrhage and post-operative pneumonia is considerably diminished. I am glad to say that during the past twelve years a marked change for the better has taken place as to the need of post-operative hospital care for tonsil cases. For example, in 1913, in a report made by me to the New York Academy of Medicine, it was found that of twenty-two hospitals and dispensaries questioned by the New York City Visiting Committee of the State Charities Aid Association, nine lived up to their obligations and kept their patients approximately 24 hours or longer for observation and treatment. In four of the other institutions, the children were allowed to go home directly after operation. In seven clinics they were kept from one hour to twenty-four hours, usually from one hour to three hours. One well known clinic sent its patients home "as soon as sufficiently recovered from the anaesthetic," notwithstanding the fact that its operators always perform a total enucleation of the tonsils under chloroform or ether. Two other clinics performed tonsillectomies and allowed the children to go home two hours later. This report awoke the school authorities, the New York City Department of Health and the Public Health Committee of the Academy of Medicine to the need of a radical change, which was promptly recommended. Consequently, at the present time, practically all good hospitals keep their tonsil cases in the wards at least through the night following operation. The principal offenders of today are private physicians who operate in their offices or in the homes of poor patients who live in crowded, unsanitary surroundings.

Dr. Lewinski-Corwin, writing for the Public Health Committee of the New York Academy of Medicine, in the *Medical Record*, May 14, 1921, has called attention to the fact that "the loss of weight following operation stands in inverse ratio to the number of days in bed after the operation and the regaining of weight is much more rapid in cases which have had a few days' rest."

Again, when I compared the post-operative cases seen in New York in 1913 with the post-operative cases observed in Nassau County during the present study, I was tremendously impressed with the great improvement which has

taken place in tonsil surgery during the past twelve years.

For example, among the 309 school children examined in Nassau County, I found 37 who had already been operated upon, some in Nassau Hospital, some in Glen Cove, and others in New York City before moving to Long Island. In only one of the 37 Nassau cases, did it seem necessary to advise re-operation. Further, there were no mutilations of the soft parts. Going back once more to my paper of 1913, I found that of 89 New York City children, who had been operated upon, 9, or approximately 10 per cent, received mutilations of the soft parts adjoining the tonsils. Of 52 New York cases operated upon with general anaesthesia, 12, or 25 per cent were poorly done.

While the number of operative cases (37) examined by me in Nassau County is too small for reliable data, yet the results observed certainly indicate that the tonsil operation had greatly improved during the past decade.

SUMMARY

1 My studies indicate that there are today over 21,000 children in Nassau County who need treatment for adenoids and tonsils.

2 During the past year less than 1,000 were treated in the hospitals of the County.

RECOMMENDATIONS

1 More hospitals should be built in various centers throughout the County.

2 Greater utilization should be made of the present hospital facilities.

3 Adequate salaries should be paid school physicians to insure good work on the part of the doctors.

4 Every public school should have a resident nurse in daily attendance, preferably on full time.

5 After a child has been examined by the school physician and the defects noted on his card, a reliable follow-up system should be instituted so that the recommendations of the physician be carried out.

6 All children, who can afford to pay, should be encouraged to have their adenoids and tonsils removed in the private or semi-private service of the hospital. If this is done, there will be more ward beds available for the deserving poor who are unable to pay. In order to make this possible, the rates for the semi-private patients should be as moderate as is consistent with the running expenses of the hospital.

7 A publicity campaign to enlighten ignorant parents, many of them foreigners, as to the necessity for adenoid and tonsil operations is essential. This can be accomplished by the daily press, by talks to both children and parents at the schools, and by the distribution of pamphlets such as that furnished by the Metropolitan Life Insurance Company.

all over the United States New York City has a number of mild cases that are known to the Department of Health They are allowed their freedom under the following conditions

- 1 They have no open lesions
- 2 There are no nasal discharges
- 3 They do not handle food
- 4 They are visited by a doctor regularly

LEADERS AND FOLLOWERS

A follower is just as essential as the leader, although he may not receive the plaudits or the financial reward that often go to a commander

Leadership requires special ability which only the few possess If all were leaders there would be confusion But usually some one has a quality in such great amount that his associates concede his superiority and his leadership

A leader implies the existence of followers Ability to do something better than one's fellows does not make him their leader He must be able to inspire others to follow his example, else he is only an individual worker

A County Medical Society consists of a few leaders among many potential followers A few doctors will serve on the important committees,

and will supply the power which makes the machinery of the Society go

A leader in a county medical society will understand its members, and will readily find some activity which will be approved by all, and be put into active operation by a considerable number Half a dozen leaders of this kind may be found in every county medical society

Leaders are often impatient because they have to do so much work, and those who should be followers are often jealous of the leaders There is a proper field for both leaders and followers That county medical society is a success in which the groups of leaders and followers each give credit to the other with entire courtesy and goodwill

THE BOY SCOUTS' COURSE IN FIRST AID

The Boy Scouts organizations offer unique opportunities for physicians to reach the public with medical information First aid is taught to all Scout troops, but the instruction is often of the old fashioned brand because it is given by amateurs and not by medical men

One of the first subjects taken up is how to stop hemorrhage A physician or trained nurse, confronted with a case of bleeding, would grasp or compress the bleeding part, and so would stop the bleeding at once Then would follow the procedure that was adopted to each particular case, be it bandaging, compression, or a tourniquet A doctor is the proper person to teach first aid in emergency wounds, and teach the boys the same procedures that he himself would follow in an emergency treatment in the field

Associated with the instruction in stopping bleeding should be an outline of how to dress a wound, especially how to use a wet dressing in order to prevent or control infection There is nothing difficult in teaching these subjects, but only a doctor knows what procedures are of essential value

The subject of artificial respiration is taught to most Boy Scouts, and fairly well, too, judging by the frequent newspaper reports of lives saved by the prompt action of Boy Scouts The Schaeffer, or prone pressure method, is the only method advocated by the industrial physician, and it is easily taught to any Boy Scout A physician can do a public health service as well as brush up his own knowledge by teaching a Boy Scout troop how to do artificial respiration

Boy Scouts are eager to learn practical sanitation, and to demonstrate it in their camping trips Here is an opportunity for a doctor to give talks and demonstrations on the disposal of excretions, the care of garbage, the selection of a water supply, and the principles of pure milk He can supervise a survey of sanitary conditions of a town, to be made by the Scouts

The Boy Scouts think a physician to be a superior being, endowed with mysterious insight into knowledge denied to common mortals The doctor has a unique opportunity to instill practical knowledge into those who will soon be leaders in civics and politics

LEPROSY

Leprosy is no longer a public health menace in the United States, although it is still prevalent in some of its possessions. Yet some of the peculiarities of the disease may throw light on the nature of other infections, especially tuberculosis.

The *Indian Medical Record*, for September, 1926 (published in Calcutta) is a special leprosy number, and is a clear review of all phases of the subject by experts who are constantly dealing with the disease. These men have a large background of experience, for there are 102,000 known lepers in India, or about one in every 3,000 of population. The actual number is probably much greater.

The writers agree that immunity to the disease is not acquired. "It would appear that Europeans are just as liable to acquire leprosy today as ever they were, or as are the natives of endemic countries, the more sanitary and hygienic conditions under which they live alone protecting them from the disease. The healthy human body forms an unsuitable soil for the growth of the lepra bacillus, but the manures and fertilizers which will render it a suitable soil are innumerable. Among them may be mentioned other accompanying diseases, as well as laziness, overwork, irregular habits, insanitary conditions, and any of the countless causes which lower the general resistance of the body."

The bacilli are discharged in great numbers from open sores and inflammatory excretions, yet they cannot be grown in artificial media or in lower animals. "In spite of many attempts, no immunological test, either serological or allergic has yet been developed that can be used practically in diagnosis or prognosis."

"Since study of toxin production by a bacterium is carried on chiefly with culture, little can be said concerning toxins of the leprosy bacillus except in a negative way."

"In spite of the incalculable numbers of bacilli they harbor and the large numbers that are undoubtedly being destroyed all the time, lepers often go for many months and even for years with very little general disturbance. During this time the tissue and vital organs (including the kidneys) as seen in lepers dying of other conditions, show surprisingly little degenerative change."

The groups of tissues usually affected by the bacilli are in their order of frequency 1, the nerves, skin and superficial lymph nodes, 2, the nose, throat and testes, and to a less degree the liver and spleen, and the veins leading away from the skin areas, 3, the lungs, kidneys, and other organs are rarely affected.

"The liver and spleen usually contain bacilli, often in abundance, but these have little effect on the organs structurally or functionally, and they disappear readily as cases improve."

The method of obtaining material for a bacterial examination of suspected tissue is given as follows:

"1 Cleanse thoroughly the area to be examined (with alcohol, or soap and water, or even ether or gasoline), to remove dirt and grease, which in unclean skins often contains acid-fast particles.

"2 Pinch up the skin, to compress. This minimizes bleeding and may prevent any pain (pressure anesthesia).

"3 With a small sharp scalpel or other instrument make a small but real cut (1 to 2 mm deep), to get well into the infiltrated layer.

"4 If blood or lymph exudes, wipe off and discard. The material for examination should be comparatively dry.

"5 With the knife-point *scrape* the bottom (V) and walls of the cut, to obtain actual tissue juice and pulp.

"6 Rub this on a clean slide preferably over a small area. Dry and fix with heat as usual."

As to prognosis, leprosy is often curable, and is self-limited, especially in the young. "Some cases are very mild, and not a few show a marked tendency to subside and undergo natural cure."

The treatment, like that of tuberculosis, consists largely in a hygienic mode of life, and the treatment of associated conditions, such as syphilis. Chaulmoogra oil is an ancient remedy which is used now more than ever before. The theory of its action is that it excites the formation of lipases which dissolve the fatty covering of the bacilli and permit the serum of the body to act directly on the protein of the bacilli.

As to prevention, "The key to the leprosy problem is really 'Save the children.' The little ones are exposed to contagion to an appalling extent. The same cups and spoons, sleeping with leprous parents, constantly in the same room, hugged and kissed by a leprous mother, crawling on the floor of the room where expectoration or the discharge from ulcerated feet may have contaminated the surface, these little ones are indeed in grave peril. Isolation at the earliest possible age of healthy children of lepers is the most important measure of all in the endeavor to stamp out this loathsome pest."

The frequency of white areas on the skin of lepers gives rise to the suspicion that any white area of the skin indicates leprosy. Leucoderma is a rather common condition that is often due to causes unrelated to leprosy, and is amenable to treatment, and often disappears spontaneously. The Biblical form of "leprosy white as snow" in which miracles of healing occurred was probably leucoderma.

Leprosy probably exists in unrecognized forms

MEDICAL PROGRESS

Prevention of Accidents of Spinal Anesthesia by Injections of Cerebrospinal Fluid—Professor Daniel of Bucharest mentions the accidents due to the shock of intraspinal injection which are expressed by many and varied symptoms involving the neurovascular apparatus and especially the vegetative nervous system. This shock may be precocious and manifested by severe untoreseen symptoms, such as cardiac syncope, respiratory syncope, or even death itself, but as a rule its effects are tardy and at times so slightly marked as to be overlooked. There may be pallor of the face, cold sweats, nausea and vomiting, cold extremities, cyanosis, superficial respiration, obstinate frontal headache (usually associated with vertigo and vomiting), disturbance of pulse and temperature, etc., etc. The mechanism of these accidents and the question of prophylaxis have been widely debated but hitherto with but little success. Presumably the accidents occur by preference in those especially predisposed. Among the views which have seemed most plausible is that of Leriche, which attributes much of the untoward happenings to disturbance of tension in the spinal canal. He first injected intravenously distilled water, which was followed in other hands by the substitution of saline or glucose solutions. It occurred to the author to experiment with injections of cerebrospinal fluid, at first subcutaneously. The subject who is to receive spinal anesthesia has 10 to 20 cc of his cerebrospinal fluid withdrawn and at once injected under the skin or into a vein. The author carried out the tests on a hundred patients, in 34 with subcutaneous and in 66 with intravenous injections. While in both cases there were but few accidents from the anesthesia the intravenous route appeared to have a slight but well marked advantage. Thus far no explanation of the mechanism is forthcoming but the author is enthusiastic over his discovery and wishes an extensive trial made at the hands of the surgical profession.—*Bulletin de l'Academie de Medecine*, Oct 5, 1926

Allergic Diseases of Childhood—George A. Campbell presents a study of 77 children with symptoms of protein sensitization. In 57 of these an accurate diagnosis could be made, while in 20 the diagnosis was not made for various reasons. The series included 32 cases of eczema, 12 of asthma, 9 of both eczema and asthma, 16 of chronic upper respiratory infection and a few cases of hay-fever and urticaria. On the basis of his observations in this series he concludes that multiple sensitization to foreign proteins is the rule in allergic children. An allergic heredity

was present in 42 per cent of the cases. Eczema in breast-fed children responds to treatment more readily than in any other group. When due to foodstuffs, eczema tends to disappear spontaneously at two years. Asthma due to foodstuffs is relieved by vomiting. In these cases silk proteins gave more positive reactions than any other protein found in clothing. Desensitization should begin with minute doses (1/1,000,000), otherwise fatal reactions may occur. Hay-fever in children responds well to treatment, if all sensitizing pollens are used. Retests should be made annually to determine the necessity for further treatment. The results of attempts at desensitization in urticaria and cyclic vomiting have been disappointing.—*Canadian Medical Association Journal*, September, 1926, xvi, 9

Alkalosis—Most studies concerning alkalosis as a surgical condition have been focussed on its occurrence in cases of pyloric, duodenal, or high intestinal obstruction, the result of a disturbance in the motor function of the upper gastroenteric tract. Frederick A. Bothe (*Annals of Surgery*, October, 1926, lxxxiv, 4) reports cases following appendectomy, cholecystectomy, perforated necrotic diverticulum, and herniotomy, thus demonstrating that alkalosis may occur as a postoperative complication in conditions not referable to the upper digestive tract. It is important to recognize alkalosis in cases of pyloric and duodenal obstruction before operation, as treatment at that time decreases operative risk. In arriving at a diagnosis of alkalosis one cannot always depend on the clinical picture. Persistent vomiting, evidence of marked dehydration, diminished urinary output, and the presence of uremic and tetanoid tendencies are the findings which would establish the diagnosis clinically. However, the changes in the blood chemistry are more constant and should be studied early in cases of persistent vomiting, so that treatment may be instituted before too great renal damage has occurred. The changes in the blood chemistry are quite constant; there is a decrease in the blood chlorides, a rise in the blood nitrogen, and elevated carbon dioxide combining power. In the preoperative cases immediate surgical intervention is not necessary. Medical treatment, however, is indicated, consisting of repeated gastric lavage to relieve stasis, and physiological saline glucose (10 per cent) to combat the depletion of chlorides and renal insufficiency. In the postoperative cases, alkalosis is more serious, and while the above treatment may be effective in the milder cases, in severe cases 500 cc physiological saline and 500 cc of 10 per cent glucose intravenously

COUNTY MEDICAL SOCIETY NEWS

The County Medical Societies are supplying this JOURNAL with more news of their activities than ever before. Moreover, their activities are of an increasingly varied nature. Two societies, for example, whose meetings are recorded in this issue, report that they are promoting a movement

for County health officer units in their counties. The records in this and preceding issues will furnish the information and inspiration for all other county societies in the State.

Let us set the ideal "A published record from every County Medical Society."

 LOOKING BACKWARD

THIS JOURNAL TWENTY-FIVE YEARS AGO

There is not much that is really new in medicine in these modern days. The doctors a generation ago had plans for unity and cooperation in medical progress. Some observers go so far as to say that the same medical ideas recur in the Medical Journals every five years.

This Journal for November, 1901, records the establishment of a Bureau of Information for the benefit of the members of the State Medical Association, but what the outcome was does not appear. The announcement reads:

"A Bureau of Information—Pursuant of its constant purpose to be of benefit to its members in every proper manner, both professionally and materially, the Council of The New York State Medical Association has decided to establish, at its Editorial and Business Offices, 64 Madison Avenue, Manhattan, New York, a Bureau of Information every facility of which will be at the service of all members of the Association entirely free of expense.

"It will be within the province of this Bureau to furnish the most accurate information obtainable relative to the price and quality of any desired article, whether for medical, surgical or general use. As will be seen, the scope of the Bureau of Information is wide, and applies with equal directness to materia medica, surgical instruments, library, office furnishings, carriages, or house equipment. In short, the Bureau will act as agent, without recompense, for any member of the Association who may desire information relative to commercial products of whatever nature.

"The Council *does not desire, however*, that the Bureau of Information shall act as purchaser, or handle monies in the fulfillment of its functions. It is deemed advisable that all financial transactions shall be between member and seller di-

rect, the Bureau using its knowledge of the well-nigh limitless commercial facilities of Greater New York to secure for members the most satisfactory quotations from the largest and most reliable commercial establishments in their respective lines. No commissions or other remuneration of any character will be accepted by the Bureau for its labors, either from seller or purchaser.

"The Council, in deciding upon the establishment of the Bureau of Information, is guided by commercial rather than philanthropic considerations. It is at once apparent that in no other way can the value of The New York State Journal of Medicine and the Medical Directory of New York, New Jersey and Connecticut be brought so favorably or so forcefully to the attention of the business community as to demonstrate in this practical manner the sustained and widespread interest of the members in their Association or in its publications. The business office of The New York State Journal of Medicine is in a position to carry forward the work of the Bureau of Information in a manner which would be impossible of accomplishment for any medical or other journal published primarily for profit.

"To summarize, the benefits to be derived from the Bureau of Information are mutual. Through it, members may secure accurate data as to new and approved commercial products, together with the best obtainable quotations. At the same time they greatly strengthen the position of The New York State Journal of Medicine and the Medical Directory of New York, New Jersey and Connecticut by demonstrating in the most forceful manner the truly great power of organization as exemplified by The New York State Medical Association."

logical process had been going on for a long time. In two patients with cardiac asthma and pulsus alternans, and in two with cerebral thrombosis, there were marked prodromal symptoms before the angina manifested itself. In seven cases the prodromal symptoms consisted of dyspnea, palpitation, and fatigue on moderate exertion with other signs and symptoms indicating myocardial impairment before the development of angina pectoris. It is therefore probable that the pathological process which eventually produces the symptoms of angina pectoris is a prolonged one and that there is involvement of the aorta and coronary arteries long before anginal symptoms develop. These facts serve to emphasize the importance, in the prevention of angina pectoris, of giving careful attention to premonitory symptoms such as those mentioned above.

Some Points in the Prognosis of Auricular Fibrillation—H. Wallace Jones (*Lancet*, Sept 25, 1926, ccl, 5378) affirms that it is impossible to overemphasize the importance of auricular fibrillation in disease of the heart, since more than one-half of the patients dying of heart failure show this abnormal rhythm at some time or other before death. The dominant factor in the prognosis is the condition of the heart muscle. If the patient is quite unaware that the change from the normal to the abnormal rhythm has taken place, it shows, as a rule, that the heart muscle is fairly good, and is a much more favorable sign than if the change had been accompanied by severe distress and evidence of sudden heart failure. In one type of auricular fibrillation, not accompanied by marked distress, however, the outlook is unsatisfactory—the type in which the heart rate remains persistently low. In this type there is usually marked myocardial damage. Factors indicating an unfavorable prognosis are limitation of response to effort, cardiac enlargement, valvular disease, and failure of the fibrillation to respond to digitalis. Quinine sulphate, when it reestablishes the normal rhythm, improves the outlook considerably, though the tendency of the heart muscle is to revert to fibrillation. From a comparison of the two main groups of fibrillation, the rheumatic type and the senile type, Jones concludes that auricular fibrillation is of more serious significance in senile than in rheumatic heart disease. In cases of mitral stenosis the presence of fibrillation makes little difference in the expectation of life. In aortic regurgitation the expectation is better when fibrillation is present than with a normal rhythm. The prognosis is more favorable with aortic regurgitation than with mitral stenosis. With marked cardiac enlargement the outlook is more grave. The expectation of life is longer

in females than in males. The electrocardiographic appearances in auricular fibrillation are of two types, the coarse type and the fine type. The average expectation of life for typical examples in these two types is about the same. The presence of a bizarre Q R S complex is of most significance in the prognosis.

The Communicability of Rheumatic Disease—In a review of the literature, Abram Joseph Abelloff and Irwin Philip Sobel (*Archives of Pediatrics*, September, 1926, cliii, 9) find many instances in which two or more cases of rheumatic fever have occurred in a single house. To this they add data obtained from reports by chiefs of heart clinics in various cities in the United States in reply to an inquiry undertaken by Dr. Haven Emerson. Information was sought as to the family history of patients (Group A) who presented manifestations of rheumatic infection (chorea, acute rheumatic fever, or rheumatic cardiac disease), and patients (Group B) who came to the general outpatient services with conditions other than those due to rheumatic infection. The data collected concerned 241 patients—139 in Group A, and 102, in Group B, serving as controls. In the latter group of families with no presenting case of rheumatic infection only 14.7 per cent had one or more members afflicted with the disease, while in the members of the families of Group A the incidence of rheumatic disease was almost twice as great. Adding these figures to those of other investigators it was found that of 1,031 families with an original case of rheumatic infection, 47.5, or 46 per cent had one or more additional cases, while in only 13.2, or 19.4 per cent, of 677 families with no presenting case of rheumatic infection, was any case of rheumatic disease discovered. Although the high incidence of rheumatic disease in certain families may in some measure be due to hereditary or environmental influences, the figures are nevertheless so striking that the possibility of the direct communicability of the disease must be seriously considered. They indicate the importance of carefully examining other members of the family for manifestations of rheumatic infection where one member is afflicted with the disease. They also suggest that precautions should be taken that at least the more intimate forms of contact with others in the family be avoided.

A Clinical Type of Cholelithiasis Resembling Renal Disease—Rupert S. Corbett and Carleton B. Pierce (*Surgery, Gynecology and Obstetrics*, October, 1926, cliii, 4) reports two cases in which the clinical picture was suggestive of renal disease, but which, after complete examination, proved to be cases of cholelithiasis. In one case there was blood in the urine

should be administered two or three times daily. The blood chemistry should be checked while intravenous therapy is being used.

Etiology, Diagnosis, and Treatment of Chronic Indigestion—John M. Flude, writing in the *Therapeutic Gazette*, September 15, 1926, 1, 9, states that chronic indigestion may be caused by intragastric or extragastric conditions, the extragastric causes being the most common. The etiology of most chronic digestive disorders may be explained by two factors: first, ptosis, and second, bacterial infection. The symptomatology is rather confusing. Keith mentions that most of the symptoms are due to ptosis alone, and this may well be, as it is the prime factor in their production. He classifies the symptoms as circulatory, gastric, nervous, and intestinal, especially constipation. The writer is inclined to think the symptoms are produced chiefly by interference with the proper blood supply. Relief of the symptoms when one assumes the horizontal posture is a quite common occurrence. Infection of the upper gastroenteric tract quite frequently occurs as the result of the repeated swallowing of infected material from the nose, throat, mouth, and bronchial tubes. Ascending infection by the colon bacilli is too well known to require discussion. Careful x-ray examination is vitally necessary for evidence of intragastric pathology and of the reflex disturbances of the stomach arising from secondary infection of the duodenum and galltract. Treatment consists in the removal of all foci of infection when possible. Abdominal support is vitally necessary for the successful relief of ptosis. Duodenal drainage of an inflamed or infected duodenum and galltract, and autogenous vaccines are valuable aids in eradicating infection.

Relationship Between Gastric Ulcer and Carcinoma of the Stomach—John S. Lawrence and A. V. Bock, in an attempt to compare the clinical findings in these two conditions, present a study of 98 cases of carcinoma of the stomach and 48 cases of ulcer of the stomach. The majority of the cases were confirmed by operation, and an appreciable number were further confirmed by pathological examination. The principal points brought out are as follows. In the majority of cases of ulcer of the stomach the initial symptoms occurred about twenty years earlier than in the majority of persons with gastric malignancy. The average duration of symptoms prior to entry into the hospital was approximately eight years for 40 of the 48 cases of gastric ulcer. In the 96 cases of carcinoma the average duration of symptoms was approximately two and a half years. There were 11 cases (11.3 per cent) of gastric malignancy in which the duration of symptoms was five years or over. On the basis of duration of symptoms alone, it would ap-

pear that 10 per cent would be a high value for the incidence of carcinoma in ulcer of the stomach. There is no real difference in the two conditions so far as sex is concerned. Slightly over one-half of 29 cases of ulcer (58.6 per cent) in which a statement concerning appetite was made, had such recorded as "good or better," as against one-fourth (26.7 per cent) of the cases of carcinoma. There is a more rapid loss of weight in gastric malignancy than in gastric ulcer. Gastric analysis showed free hydrochloric acid absent in the fasting contents in approximately one-third (30 per cent) of the ulcers as against nine-tenths (87.7 per cent) of the cancer cases. Only one-tenth of the cases of gastric ulcer showed absence of free hydrochloric acid in the contents removed after a test meal, as compared with about three-fourths (70.8 per cent) of the cases of gastric malignancy. Occult blood in the feces was found about three times as often in the feces of patients with carcinoma of the stomach as in patients with ulcer. There was no difference of note in the two series of cases as regards red blood cells or hemoglobin. The outstanding physical finding differentiating these conditions was found to be the presence or absence of a palpable abdominal mass. Over 52 per cent of cases with carcinoma had a palpable mass, whereas only one case of gastric ulcer gave this finding. The most common initial symptom in both series of cases was epigastric pain. Any adult with unexplained gas on the stomach, heartburn, or constipation, should have a roentgenological examination. These observations seem to indicate that there is not a very close relationship between the two conditions.—*Boston Medical and Surgical Journal*, September 30, 1926, cxcv, 14.

Prodromal Symptoms in Angina Pectoris—Morris H. Kahn (*American Journal of the Medical Sciences*, September, 1926, clxxii, 3) has analyzed a group of 82 cases of angina pectoris, of which 25 (30 per cent) presented prodromal symptoms. There were 10 cases with substernal burning sensation or attacks of pressing pain or burning sensation in the epigastrium. In a few the symptoms of burning manubrial pain and epigastric distress were combined. In 4 cases, or nearly 4 per cent, typical attacks of angina were preceded by symptoms which were not characteristic of angina. In these cases the first attack noted by the patients indicated some sudden cardiac change and consisted of sudden weakness, faintness, darkness before the eyes, or falling to the ground without loss of consciousness and without any chest pain. In subsequent attacks pain became the dominating feature. In one case the non-typical attack occurred eight years before the angina. In the interval there was continued substernal burning pain with dyspnea after moderate exertion, indicating that a patho-

TONSILLECTOMY—HEMORRHAGE

This action was brought to recover damages for alleged negligence in the performance of a tonsillectomy. It was charged that the defendant physician failed to make a preliminary examination and operated upon the right tonsil in such a manner as to remove a large portion of the flesh and sever an artery and failed to take the proper steps to control the hemorrhage, which resulted in an infection of the plaintiff's throat. The plaintiff further claimed that he was unconscious for a period of several hours and lost a great quantity of blood, that by reason of the loss of the blood he became constitutionally weakened and in a nervous condition and for a period of time after the operation was unable to consume any but liquid foods. He claimed that he was unable to follow his occupation of a salesman for a period of four months and that after the operation he was compelled to engage the services of other physicians to remedy the injury caused by the defendant.

This patient had called on the defendant on January 8th. He was of a nervous type and asked that the physician be kind to him. After a thorough examination arrangements were made with the patient for the performance of a tonsillectomy, the same to be done at the physician's office on January 15th. The operation was performed, the tonsils being removed by the snare method. Upon completion of the operation the patient was put into the rest room. About half an hour thereafter the physician found that the patient had a mouthful of blood. He then brought the patient into the operating room, but upon examination found no bleeding point. The blood, however, seemed to have come from the right side of the throat, but the point from which it came could not be determined by the physician. A sponge was placed at the right side of the throat, the bleeding stopped and the throat became dry. About fifteen minutes later the patient had another mouthful of blood. It seemed to the physician that the patient vomited the blood, his throat showing no bleeding point.

The physician then called a colleague in consultation, who examined the throat and found it dry. His colleague was about to pack the throat and leave when he was requested by the defendant physician to remain. The consultant, upon examination, found no open vessels, no ragged tissue and no bleeding and that

the operation was complete. When the consultant was about to leave there was another gush of blood from the patient. The consultant then cleaned out the cavity, but was unable to find any bleeding point. A sponge was then sewed between the anterior and posterior pillars on the right side. Hemostatic serum was injected and the cavities were painted. The patient was then returned to bed, but in about ten minutes there was another gush of blood and the sponge was ejected from the mouth.

The patient having been weakened by the loss of blood, it was decided by the defendant physician and the consultant that the patient had better be sent to a hospital. An ambulance was then called and the patient removed to a hospital. That evening the defendant physician called at the hospital and was advised that the patient was doing well and that there had been no bleeding since his entry into the hospital. On the following day he again visited the patient at the hospital, who at that time was in a wheel chair, and he advised the defendant that he felt comfortable but complained of soreness in the throat, particularly on the right side. The defendant also visited him at the hospital on the third day, January 18th, and the patient was discharged on the following day.

At the hospital the physician had requested the patient, upon his discharge, to call on him at his office which he did upon his release from the hospital. Upon examination no bleeding was found, but the normal amount of reaction and tenderness from the operation were found. The defendant again saw the patient on January 25th and found the throat to be healing, there being no bleeding and no sloughing of the tissues. This was the last time the patient was seen by the physician.

The action remained on the calendar for some time and when it had reached a position to be tried, the plaintiff not being ready to proceed, on motion of the defendant physician the complaint was dismissed and a judgment of dismissal was entered. Thereafter the plaintiff appealed to the Appellate Court from the order dismissing the complaint. This appeal was not perfected and a motion was then made to dismiss the appeal for lack of prosecution of the same, which motion was granted, finally terminating the action in favor of the physician.

and frequency with burning and smarting. Specimens obtained by ureteral catheterization showed red blood cells, white blood cells, epithelial cells, and a few colonies of staphylococci. The administration of tetra-iodophenolphthalein and r-ray examination revealed shadows resembling those of gallstones, and at operation four stones were found in the gall-bladder. Following the operation the urinary condition cleared up. The second case was quite similar though the hematuria occurred only at intervals and no red blood cells were found in the specimens examined. Based on the r-ray examination a diagnosis was made of cholecystitis and cholelithiasis. After operation the urine no longer showed abnormal constituents. These cases were associated with large gallstone formation, a moderate degree of change in the gall-bladder wall, and a fair shadow of the viscus after the administration of tetra-iodophenolphthalein. The last-named finding is indicative of normal liver function, patency of the cystic duct, and good power of bile concentration by the mucosa, according to the standard of Graham and Cole. These facts are difficult to reconcile with the accepted view of the etiology of gallstones. They tend to the view of a chemical rather than an infectious basis for gallstone formation. The gallstones might then be considered to be a cause rather than an effect of the cholecystitis.

The Rectal Administration of Epinephrine—William C Meninger and Harlan S Heim (*American Journal of the Medical Sciences*, September, 1926, clvii, 3) call attention to the fact that comparatively few studies of the effect of epinephrine given by mouth or rectum have been made. They have made 31 observations of the results of rectal administration of the drug. In 64 per cent of these there was a blood pressure rise of over 10 mm, and in 50 per cent a rise of over 20 mm of mercury. The maximum effect was reached in an average time of 40 minutes after administration. The duration of the blood pressure rise was 45 minutes longer. The pulse was slightly decreased or remained constant in 18 cases while it was increased in 13 cases. Other systemic or local effects most frequently observed were tenesmus, desire to urinate, abdominal cramps, sweating, epigastric distress, and relief of respiratory difficulty in asthmatic cases. It was found that the rectal absorption of epinephrine in relatively large doses is unreliable, but in the positive cases the systemic effect, while slower in reaching a maximum, persisted over a much longer time than when the drug was given hypodermically. The rectal method of administration should be of advantage in cases requiring a prolonged effect and repeated doses of epinephrine, as in asthma or Addison's disease.

Röntgen Diagnosis of Syphilis—Dr Carlos Heuser of Buenos Ayres announces the discovery of a new radiologic sign of syphilis—the presence of exostoses on the bones of the pelvis where they are not susceptible to palpation. In a number of cases the picture was symmetrical and typical. Since no other disease is able to produce lesions of this type the sign is pathognomonic. The exostoses are naturally a chance find or at least were so at the outset as in the case of a woman who was radiographed for appendicitis. The site of the lesions is anywhere in the pelvic girdle—the pubis, ischiopubis, iliac bones and crests. The cases occurred most commonly in the age period 20 to 50, but the author has also encountered the lesions in children and old people. In those who are above 55 care must be taken in excluding calcifications and ossifications at the muscular insertions, which are physiological. Other locations of these exostoses brought out in roentgenograms are in the region of the atlas, axis, and occipitovertebral articulation. The patients who presented the lesions gave a positive Wassermann. The diseases for which the roentgenograms were originally made show some strange coincidences, for no less than 20 presented gastric ulcer while 9 others were prostatics.—*Revista de la Sociedad de Medicina Interna*, July, 1926.

Pyemia of Tonsillar Origin—Uffenorde contributes an article on post-anginous pyemia in the *Deutsche medizinische Wochenschrift* for September 24, 1926, which appears to be taken from his monograph on the same subject, probably as yet unpublished, as no reference is given. This work comprises all cases recorded to date in the world literature. In recent years, the author states, there have been many cases reported of all sorts of systemic infection from both acute and chronic tonsillitis—lymphatic, toxic, septic, pyemic, and metastatic. At the Hamburg-Eppendorf Hospital 15 cases of pyemia have been recorded in the past 7 years. Fraenkel reported 6 cases in which the jugular vein was ligated. Melchior and Ries quote 4 recovered cases of the severe metastatic type. It is not the tonsil itself which seems to be concerned in the pyemic type but a peritonsillar phlegmon, which explains why the author prefers the term anginous to tonsillar. He states in passing that our knowledge of the local pathology in these conditions is defective. Regarding treatment a question of importance refers to ligation of the external jugular vein to avert some of the dangers of pyemia. In the cases cited by Fraenkel, however, death resulted sooner or later despite ligation, nevertheless, since pyemia is due to local phlebitis, ligation is indicated in theory if done early enough. Some of these cases seem to have terminated in thrombosis of the intracranial sinuses.

involved and the opening not widened. No attempt was made to close the incision, which was packed, Dakin's solution also being used.

The condition of the patient not improving and she growing more irritable and permitting no one but the defendant physician to dress the wounds, which he had to do at times under an anaesthesia, on April 25th, under a gas-ether anaesthesia, a second exploratory operation was performed. At this time the old Killian incision was laid open and the edges of bone trimmed up. The dura was felt along right cribriform plate but the granulations on the dura were not disturbed. Incision was extended up to median line of the forehead and the bone over the frontal area exposed. Two holes were drilled through the cortex and connected until fair sized openings were made about one inch by one-half inch. The pressure on the dura was noted and on incising the dura brain material herniated through. A blunt needle was used to make the exploration. A lack of natural resistance was noted with masserated brain tissue encountered. Although the exploration was carried out in several directions, no pus was found, or at least could not be drawn out into a syringe. The curved separator seemingly by its own weight was carried into what seemed to be a cavity, probably at a depth of about two inches. A culture was taken of the existing material which very much resembled pus, but no suitable amount could be drawn into the syringe. A two-inch drainage tube was inserted and stitched in place by sutures through the periosteum. The ethmoid and frontal area was packed with gauze and dressings applied. After this operation the patient still continued to be intractable, at times being morose and at other times hilarious and boisterous. She refused to permit the nurses and internes to attend her and would not obey their orders or instructions and interfered with the dressings of the operative wounds. She was seen daily by the defendant physician, who personally did the dressings. Her condition growing gradually worse, the superintendent of the hospital advised that she could no longer be kept there as a patient and on May 27th she was removed, in a delirious condition, to another hospital. At the second hospital she was confined to the psychopathic ward for about a week and then

moved to another ward. On July 7th a spinal fluid was taken which showed the presence of staphylococcus aureus. She was also suffering from a bilateral choked disc. On this date she was examined by the neurologist at the hospital, who advised perimetry and attention to scotoma and if found to be negative he then advised ventriculography. This neurologist made a diagnosis of probable frontal abscess. On July 10th a perimetry was taken and the chart showed normal fields and no enlargements of blind spots and no scotoma. Two other attending physicians at this hospital examined her and advised a ventriculography, which was done on July 13th. The ventricle entered at first puncture 27 cc. of fluid was removed and 35 cc of air injected, with negative findings. At about 10 30 P M of July 13th a consultation was held and it was decided that respiratory failure, which had set in, was due to the pressure of medulla. She was then operated upon and an incision made over the frontal region at outer angle of the prior incision made for ventriculography down to the superciliary cover and flap dissected over the hernia which resulted from the prior frontal exploration. The frontal bones were removed, the dura was opened, the right frontal lobe was found bulging. No exploration of the brain was made, the dura was not sutured. Drains were inserted, although no definite pus was seen. No anaesthesia was used as none was necessary, the patient being in a coma. She died at about 6 30 in the evening of the day following this operation. The parents refusing, no autopsy was performed and the cause of death as given on the death certificate was "Abscess of brain with contributory cause of pulmonary edema."

When this action finally came on for trial the plaintiff, in an attempt to support the complaint, called as witnesses several of the physicians who had attended the patient at the first hospital and who had assisted the defendant in his operation and treatment of the patient. The testimony of these physicians, however, did not establish the plaintiff's cause of action but substantiated the defendant's treatment and at the close of the plaintiff's case, on motion on behalf of the defendant, the plaintiff, not being able to establish her cause of action, the complaint was dismissed.

CLAIMED BURN FROM THERAPEUTIC LAMP

Here the patient claimed he was suffering from a tightening of the muscles and a stiffening of the joints of the left leg and foot and after consulting the defendant physician was advised to undergo a baking process of said leg and foot, that the physician undertook to render such treatment for the purpose of relieving the condition of which the patient complained, that in his treat-

ment the defendant was negligent, careless and unskillful and allowed the plaintiff's limb to remain in the baking apparatus for too long a time and furnished too great an amount of heat to the apparatus, causing the patient's left leg and foot to be burned through the skin, that by reason of the burn the skin dried up and came off, that the leg and foot became infected and that the patient

SINUSITIS—BRAIN ABSCESS

An administratrix sued a physician to recover for the death of her decedent, which she charged was due to the negligent and careless treatment of the defendant. In her complaint she alleged that on February 16th the decedent consulted the defendant physician, who had held himself out as a specialist in the treatment of eye, ear, nose and throat conditions, in an effort to be cured of a minor ailment and occasional headaches, that by reason of the improper treatment of the physician, the bones and tissues of the decedent's skull became diseased and infected and suppuration and decay were occasioned thereby, that her physical and mental health were impaired and that she died by reason thereof. It was further charged that he neglected properly to care for the decedent subsequent to the performance of an operation on February 16th, that he ordered her to be discharged from the hospital on February 21st with a quantity of gauze packing remaining in her nostril extending upward and into the frontal sinus, that thereafter and until March 30th he was negligent and careless in his examination of the decedent and failed to discover the presence of the gauze packing in the nostril and did not remove the same until the latter date. The decedent was about nineteen years of age at the time of her death and, it was claimed, in good health and possession of all her faculties and engaged as an office clerk prior to the operation performed on February 16th.

This patient had been referred to the defendant by the family physician with the complaint of constant headaches and a chronic nasal discharge. A tentative diagnosis was made of congestion of the sinuses. On February 16th she entered a hospital as a ward patient. X-rays were taken and an interpretation made of chronic ethmoiditis of the right side. The patient also had a deflected nasal septum on the right side. On the latter date there was performed a submucous resection of the nasal septum and an extirpation of the right ethmoid, scraping out the cells, dead bone and the diseased tissue, together with the suppurative process. This operation was done under a general anaesthesia. There was no excessive bleeding and no packing of any kind was used during or after the operation. The operation was performed between two and four o'clock in the afternoon and the patient was returned to bed in good condition. The defendant physician did not see the patient again until the following morning. From the nurses' bedside notes it appeared that at about six o'clock in the afternoon the patient was still in good condition and conscious. On the hospital report there appeared a notation that there was considerable bleeding the first of the evening, the right eye was swollen and discol-

ored, which condition existed on the following morning, February 17th. There was also a nurse's note on the record that at 9 30 A. M. February 17th, a plug was removed from the throat by the house surgeon. On his arrival at the hospital on the morning after the operation the defendant physician was told that during the preceding evening the patient had suffered from a secondary hemorrhage and packing was resorted to and that the packing had been removed. The decedent was an intractable patient while at the hospital, interfered with the dressings, was continually creating a disturbance and refusing to permit the nurses to attend to her. Until her discharge on February 21st she was seen daily at the hospital by the defendant. After this date she was an ambulatory patient and was seen by the defendant at the clinic. From time to time, for a period of about five weeks, her nose was irrigated with a solution of argyrol and water. She complained that the operation had not helped her and that she still suffered from the headaches and the nasal discharge. On March 30th, while the defendant was examining the decedent, he observed two or three threads protruding from the right side of the nose and with nasal forceps he removed a piece of gauze about four inches long. The nasal cavity was then washed with a saline solution and the patient instructed to return within a few days. Later, accompanied by her parents, she was seen by the defendant at his office. At this time she appeared sullen and morose. Upon examination her pulse was found slow and the condition indicated that there might be an intracranial abscess, which fact was communicated to the parents and it was recommended that she re-enter the hospital.

On April 18th she again became a bed patient at the hospital and a radiographic examination made at this time disclosed that the frontals were small and showed moderately severe involvement, the ethmoids showed moderately severe involvement and both antra showed moderately severe involvement. The defendant then consulted four of his colleagues at the hospital, after which consultation it was decided to explore the brain in an endeavor to determine the cause of the patient's condition, the procedure being consented to by the parents. On April 20th, under a general anaesthesia, the defendant, assisted by two other surgeons, performed a Kilian operation—right frontal sinus, for possible meningitis and brain abscess. On this operation frontal was found not to be involved, the ethmoids were found exenterated, with dural exposure where the cribriform plate formerly was and granulations found to cover the dura. The bridge was removed to provide drainage and the exposure widened slightly. The sphenoid was found un-

NEWS NOTES

SUFFOLK COUNTY MEDICAL SOCIETY

The Annual Meeting of the Suffolk County Medical Society was held on Thursday, October 28, 1926, in the Griffin House, Riverhead, with President J S Ames presiding and Dr Frank Overton recording.

The report of the nominating committee was unanimously adopted and the following officers were elected for the coming year:

President, Dr Frank Overton, Patchogue, Vice-President, Dr Frank S Child, Port Jefferson, Secretary, Dr E P Kolb, Holtsville, Treasurer, Dr David H Hallock, Southampton, Censors Dr George H Schenck, Southampton, Dr Paul Nugent, East Hampton, Dr W A Baker, Islip, Delegates to the State Society Dr W H Ross, Brentwood, Dr Guy H Turrell, Smithtown Branch, Alternates Dr J S Ames, Babylon, Dr Frank Overton, Patchogue.

The following physicians were reported favorably by the censors and elected to membership:

Dr Theodore Gallup, Smithtown Branch, Cornell, 1923, proposed by Drs Guy H Turrell and W H Ross, Dr Charles C Low, Bellport, University of Buffalo, 1896, proposed by Drs S R Corwith and Frank Overton.

Dr W H Ross, Chairman of the Legislative Committee, reported that the Practice of Medicine Act had passed the Legislature through the influence of laymen who acted largely through the solicitation of the Tuberculosis and Public Health Association, Inc. He said that so long as only the doctors advocated the bill, the Legislators were under the impression that they were acting from selfish motives, but that when about seventy-five laymen from the county urged the passage of the bill, the Legislators supported it. Dr Ross also told how the Act is now in successful operation.

Dr Guy H Turrell, Editor of *The News Letter*, reported on the action of the Comitia Minora in making *The News Letter* the organ of all public health agencies in the County, as well as the County Medical Society. The Comitia Minora, acting on the authorization of the County Society given at the Semi-Annual Meeting on May 18, had accepted the offer of the Tuberculosis and Public Health Association, Inc., to finance the issue of a larger number of copies, and that now *The News Letter* was sent to 800 persons, with the expectation that it would soon be sent to about 2,000. The County Medical Society continued to pay \$25 each month toward its support, and the Tuberculosis and Public Health

Association, Inc., was paying about \$40 for the additional copies. The total cost of 2,000 copies would be \$105 each month.

Dr Overton reported on the matter of Periodic Examinations, in the absence of Dr Williams, Chairman of the special committee appointed by the Comitia Minora. He said that 300 blanks had been obtained from the American Medical Association, and he exhibited the blanks to the members and explained that the Committee would send two blanks to each member with the request that he go to a brother physician and undergo an examination himself in order to demonstrate to the public the sincerity of the doctors in advocating the examinations.

The Secretary described the action of the Comitia Minora in advocating an educational campaign in *The News Letter* for the purpose of educating the people regarding the necessity of a better observance of the regulations regarding scoring dairies and issuing permits by the health officer. He reported that the South Side Hospital and the Southampton Hospital had equipped their laboratories with the means for making bacterial counts of milk, and that the Greenport Hospital was also taking steps in the same line.

On motion the following resolution was unanimously adopted:

Resolved, that this Society

1 Endorse and approve the articles on milk published in *The News Letter*,

2 Urge health officers and boards of health to utilize the means for making milk counts regularly,

3 Urge the appointment of a full-time milk inspector by the Board of Supervisors in order to unify and amplify the work of the health officers.

Dr W H Ross presented the following argument in favor of a county health officer:

For the better organization of the means of promoting health and preventing disease in Suffolk County, advantage should be taken of the permissive law, in existence since 1921, authorizing the Board of Supervisors to establish a county health unit under a full time health officer. Under the law of 1925 the county can have state aid to the amount of one half of its appropriations for health purposes.

The method now in use—of township and village health units—produces relatively evanescent results. A county health unit, under direction of a well trained and competent full time health officer, would make possible much wider and

suffered intense shock and pain, was unable to sleep or to work and his health was generally undermined, that he also sustained numerous scars where the leg and foot were burned and the places where the same were burned have remained tender and susceptible to pain under pressure, that he had been required to spend moneys to relieve the injury and had been prevented from following his usual occupation of a truckman

Prior to his call on the defendant the patient had been receiving treatment at a hospital for a secondary phlebitis of the left leg. The physician decided to administer light treatment to the plaintiff to relieve the condition of which he complained. He then exposed the leg to the light, placing the lamp twelve inches above the leg and using a 2,000 Watt bulb, which was covered with a cone-shaped shade. The parts of the body not exposed to the light were protected by towels. The light application was given for ten minutes. Upon turning off the light the physician found a mild erythema on the spot that had been exposed,

which he properly treated at that time. The patient did not again call upon him and no further treatment was rendered by the physician. He passed into the care of other physicians. The irritation of the skin subsequently blistered, broke down and ulcerated, but after a period of treatment it entirely cleared up.

The plaintiff sought in this action to charge this physician with the injury which he claimed to have sustained. At the time of the rendition of the treatment the patient was lying on the table with his face down. During the course of the trial the plaintiff gave testimony in his own behalf as to the distance the lamp was from his leg and the length of time the leg was exposed to the light. On cross-examination, when it was developed that he was lying in a position in which it was physically impossible to see the lamp or know how long the leg was exposed to the lamp, his story was entirely discredited and at the close of the plaintiff's case the complaint was dismissed for failure of proof upon his part.

HYPODERMIC INJECTION—BROKEN NEEDLE

In this case it was charged that the defendant physician negligently and carelessly injected a hypodermic needle into the plaintiff's arm and unnecessarily caused her to be drugged and brought under the influence of drugs, caused a hypodermic needle to be broken while in the plaintiff's arm and failed to remove the broken needle.

On September 20th at about 5 P. M., the plaintiff, a girl about eighteen years of age, was brought to the office of the defendant physician and he was requested to give her something to quiet her nerves. On examination the physician found her to be a healthy girl except that she was nervous and he prescribed bromide. The plaintiff was taken to the home of a girl friend and within about an hour, before she had taken any of the bromide, she became hysterical and the defendant physician was again called. At this time he found the patient kicking and screaming and

crying and he was requested to give her something to quiet her. He had with him a syringe containing morphine. He then sterilized the needle in boiling water, washed the girl's arm with alcohol and, while holding her forearm with his left hand, inserted the needle in the muscles of the upper arm. Just as the needle entered, the girl suddenly raised her arm, causing the needle to break. The physician then told the people who were with the girl of the breaking of the needle and advised them to take the girl to a surgeon so that steps could be taken for the removal of the needle, as he felt that this was a case for a surgeon. Shortly thereafter this malpractice case was brought against him charging him with negligence in the breaking of the needle.

The action came on for trial, and the plaintiff being unable to establish a cause of action, the complaint was dismissed.

favor of the defendant, you never know where the lightning is going to strike next. The rate is low but the satisfaction in the feeling of protection cannot be expressed in dollars and cents. There should not be one physician in this society unprotected in this matter.

At this time another most important step in preventive medicine is being sponsored by this society. We have already done a vast amount of work in the campaign for pure milk and our investigations so far have revealed conditions that account for many of our cases of so called summer complaint. The work we are doing and the results we hope for will play just as important a part in preventive medicine as health examinations and immunizations.

"Suffolk County has led the state in its work in tuberculosis and the publishing of its news to the profession and laity. With everyone doing his share this society should become the example for every other society in the state."

D. Walter Truslow, of Brooklyn, gave an address on Flat Feet, and illustrated his remarks

with a clinic of three cases supplied by Dr. Terrell and Miss Minnie Ashton, School Health Teacher of Riverhead. Dr. Truslow will write out his remarks in the form of an illustrated article, reprints of which will be available to the members of the society.

Mr. Eric Larsen, Welfare Agent for the Long Island Lighting Company, demonstrated a portable inhaler used by the Company in order to give oxygen containing five per cent of carbonic acid. The carbonic acid is a powerful respiratory stimulant and of great value in carbon monoxide poisoning, not only in severe cases, but also in mild cases in which headache and nausea are the prominent symptoms. (The use of carbonic acid in oxygen was described in an article by Dr. Henderson in the *Journal of the A. M. A.* for September 6, 1924, page 758.)

The members and their guests dined together in the Griffin House. After lunch, group pictures and movies of the physicians were taken by Dr. Overton.

TOMPKINS COUNTY MEDICAL SOCIETY

The October meeting of the Tompkins County Medical Society was held Tuesday evening the 26th, in the Chamber of Commerce parlors, Ithaca, N. Y., with about 60 members and visitors present.

The minutes of the September meeting were approved as read. The Secretary, reporting for the Comitia Minora, read the minutes of its last two meetings.

It was moved, seconded and carried that the plan for medical relief in case of disaster, as presented by the A. M. A., be and is hereby approved as recommended by the Comitia Minora, and that if the plan is finally adopted, our By-Laws be amended to conform thereto in regard to the duties of the President.

The application of Frederic C. Robbins of the Medical Advisory Staff of Cornell University, for Associate Membership was presented. It having been approved by the Board of Censors he was duly elected.

President Larkin then stated that the special subject of the meeting was to consider and discuss the advisability and feasibility of establishing a General Health District (usually termed a County Health Unit) in, of and for Tompkins County, and invited Dr. Luzerne Coville to take the Chair.

Dr. Coville introduced Dr. A. C. Burnham, Assistant in preventive medicine of the State Charities Aid Association, who gave a rather detailed outline of the subject and stated there are

now more than 300 such county health centers in operation in the United States, resulting in better coordination in the work in the different health divisions of the county when working under one directing head, the County Health Officer, who works under the general advice of the County Health Board.

Dr. Coville then introduced Dr. R. E. Plunkett of the State Department of Health who said that Dr. Matthias Nicoll, State Commissioner of Health, is thoroughly in favor of the establishment of county health units, and explained in detail the methods of organization and operation of such units, and showed that the State duplicated any county appropriations for that purpose.

Dr. Livingston Farrand, President of Cornell University, was then introduced and gave a general discussion of the subject. Dr. Farrand has had a long experience in public health movements, and stressed the point that the trend of the times, as shown in medical education and thought, is more and more toward preventive medicine. The people themselves are beginning to demand it, and the County Medical Societies should be the leaders in such matters. The physician has a false idea that his practice and income would be materially reduced thereby, but the fact is that both are increased. Dr. Farrand thoroughly favors the idea of a County Health Unit for Tompkins County, and showed how the county is favorably situated for successfully carrying out such a project.

more effectual health work. The unit of administration in a township is too small for efficiency and team work. Any sanitary or disease control, or food regulation must be county wide to obtain measurable and permanent results.

Growing experience in public health work in the county leads to the conclusion that little or no further real advance or likelihood of a permanent uplift in the promotion of health and prevention of disease will occur, unless there is a better administrative organization. The only method in sight that will do this is a county board of health. This will not do away with township health boards, but will provide organization and methods to increase their efficiency.

There is only one possible argument against this, and that is cost. It will increase expense, probably as much as ten cents per capita per year. The people of the county are quite likely to be willing to spend this amount for better health, since they are now standing the expense of a good deal of preventable sickness.

On motion of Dr. Ross, the following resolution was unanimously adopted:

"Resolved, that the Suffolk County Medical Society go on record as favoring the establishment of a county board of health unit under a full-time health officer."

After the adoption of the favoring resolution, the society voted to instruct the Comitia Minora, the executive committee of the society, to take all proper steps to bring the desirability of this county unit to the attention of the voters and of the Board of Supervisors.

Dr. Frank Overton read the following proposal:

"We wish to propose that the Suffolk County Medical Society consider Graduate Medical Education modeled somewhat after a correspondence course, according to the following plan:

"1. The County Society is to adopt the plan and provide the funds for the preliminary financing, and appoint a committee of four to have the plan in charge.

"2. A subject is to be chosen—the heart, for example—and an outline or syllabus would be developed in consultation with an expert teacher from Kings County or other available source.

"The books or pamphlets would be named for study.

"A detailed plan of reading and study would be issued, including a set of questions for self-examination, or even a written examination, if the members so desired.

"The members would buy their own books, and would pay a fee for the questions and syllabus.

"3. Groups would come together for consultation, clinics, etc. The natural groups would

be the staffs of the four general hospitals. The societies existing in the vicinity of the hospitals might adopt the course as their program for the winter.

"Dr. C. A. Gordon, of the Committee on Public Health and Education of the State Medical Society, has devised a plan for a written lecture to be sent to any group desiring it and used with lantern slides, on moving picture film, and shown by means of a projector such as that of the Spencer Lens Company.

"The object of the proposed correspondence and lecture courses is to bring the means of graduate study to individual doctors in distinction from groups."

Dr. Alec N. Thomson, Secretary of the Public Health Committee of Kings County Medical Society, explained the plan of a correspondence course in considerable detail, and offered the assistance of the Kings County Medical Society in putting it into operation.

On motion the project of a correspondence course as outlined by Drs. Overton and Thomson was unanimously approved, and the President was instructed to appoint a committee to put it into operation.

Dr. J. S. Ames gave the annual presidential address in which he said:

"It is not boasting for me to say that the past year has been a successful one for the society, the regular machinery has worked on as usual and some innovations introduced which will, I believe, work for the betterment not only of the society but of the county at large.

"In the first place *The News Letter* has been expanded so that it now represents not only the medical society but the tuberculosis and public health societies as well. This results in giving us all the news of these societies. But of more importance the mailing list has been greatly increased so that the letter reaches county and town officials and prominent people in every village. This will give people a much broader idea of what we are doing for them in our hospitals and societies. The general public is taking more interest than ever in medical topics and a sheet of this kind will give them more accurate information than they can otherwise obtain. I do not know how the press in other villages treat their physicians, but if the residents of a certain village believe all they read in its newspaper, there would not be much respect for the medical profession.

"A most important thing is being neglected by many physicians in this county as well as throughout the state, and that is taking out insurance against suits for malpractice. In your reading of journals and daily papers you cannot help noticing the increase of these cases in the courts, and although the majority of the verdicts are in

favor of the defendant, you never know where the lightning is going to strike next. The rate is low but the satisfaction in the feeling of protection cannot be expressed in dollars and cents. There should not be one physician in this society unprotected in this matter.

At this time another most important step in preventive medicine is being sponsored by this society. We have already done a vast amount of work in the campaign for pure milk and our investigations so far have revealed conditions that account for many of our cases of so called summer complaint. The work we are doing and the results we hope for will play just as important a part in preventive medicine as health examinations and immunizations.

"Suffolk County has led the state in its work in tuberculosis and the publishing of its news to the profession and laity. With everyone doing his share this society should become the example for every other society in the state."

"The lecturers will be

"Dr Albert F R Andresen, Clinical Professor of Gastro-enterology, Dr John B D'Albora, Assistant Clinical Professor of Gastro-enterology, Dr Frederick Schroeder, Assistant Clinical Professor of Gastro-enterology, Dr Julian Rose, Instructor in Gastro-enterology

"This course is to be given on Wednesday afternoons, beginning October 6, and will consist of brief and practical demonstrations and discussions of gastro-enterological diagnostic and therapeutic procedures. The members are requested to bring with them to the lectures patients who may be used for clinical material

"In general, the following outline will be followed

"October 13—General considerations of diagnosis and treatment, stressing the importance of

a simplified classification of symptoms and of dietetic procedures—Dr Andresen

"October 20—Diseases of the stomach and duodenum—ulcer, carcinoma—Dr D'Albora

"October 27—Diseases of the gall-bladder and appendix—Dr Schroeder

"November 3—Diseases of the colon,—colitis, carcinoma—Dr Rose.

"November 10—Resume of entire course, with consideration of any gastro-enterological subjects not covered previously—Dr Andresen

"Cases to be demonstrated

"October 13—1 carcinoma to show cachexia, 1 jaundice, 1 diarrhoeal, 1 peptic ulcer to show the lack of cachexia or anemia in the average case

"Please bring a gastro-enterologic case if you have any

"Dr CHARLES RAYEVSKY, President "

ESSEX COUNTY MEDICAL SOCIETY

The Annual Meeting of the Essex County Medical Society was held at the John Hancock House, Ticonderoga, N Y, October 12, 1926, and was called to order by the President, Dr Peter Noe, at 2 15 P M, with eleven members present

A report of Conference of Secretaries, held at Albany on September 9, 1926, was given by Dr Peter Noe, Willsboro, N Y. Dr Noe stated that very little was brought out

A discussion of this Conference followed

A nominating committee, consisting of Drs Dowd, Barton and J P J Cummins, made the following nominations: President, Dr W T Sherman, Crown Point, N Y, Vice-President, Dr J H Evans, Keeseville, N Y, Secretary and Treasurer, Dr L H Gaus, Ticonderoga, N Y, Censors, Drs Peter Noe, H J Harris, E C Johnson, Delegate to State Society, Dr L G Barton, Plattsburg, N Y, Alternate Delegate to State Society, Dr J Breen, Schroon Lake, N Y, Delegate to Fourth District Branch, Dr A Gersen, Elizabethtown, N Y, Alternate Delegate to Fourth District Branch, Dr C N Sarlin, Port Henry, N Y, Chairman of Legislative Committee, Dr C N Sarlin, Port Henry, N Y. These officers were unanimously elected

The Treasurer's report was read and adopted. Dr R T Saville, of Minerville, was made an Honorary Member of the Medical Society of the County of Essex

On motion of Dr J P J Cummins, Governor Smith was congratulated for his efforts in behalf of the public in furthering public health

measures which were recommended by physicians of the State

Drs Barton and Evans were appointed a committee to draw up resolution in the death of Dr C R Payne

"Whereas, Dr C R Payne, an honored member of the medical profession and a member of the Essex County Medical Society, has died since our last meeting, and

"Whereas, Dr Payne was respected and loved by all in and out of the profession, therefore

"Be It Resolved, that the Medical Society of the County of Essex express its sympathy to the family of Dr Payne and that the Secretary be instructed to publish this resolution in the County papers and to inscribe it in the minutes "

Resolution made, seconded and adopted

Dr L G Barton, Sr, First Vice-President of the Fourth District Branch, made his official visit to the Medical Society of the County of Essex

SCIENTIFIC PROGRAM

1 Hyperthyroidism and Incipient Pulmonary Tuberculosis—A Comparative Study. Dr H J Harris, Westport, N Y

2 Demonstration of Radiographs. Dr J P J Cummins and Dr M E Sargent, Ticonderoga, N Y

Reading of an Unusual Case History. Drs J P J Cummins, T J Dowd and L H Gaus, Ticonderoga, N Y

Adjournment

Luncheon served at the Moses-Ludington Hospital

Discussion was general and many questions were asked and were answered by the speakers. In response to one question Dr Plunkett presented a tentative annual budget of \$12,000 to \$15,000 for such a unit in this county, one-half of which would be paid by the State.

At the close of the discussion Dr Martin B Tinker, past President of the State Society,

moved that the President appoint a committee of three, one of which should be the Chairman, to investigate the advisability of establishing a County Health Unit of, in and for this county, to report at some subsequent meeting. The motion was seconded and carried.

Adjournment

WILBER G FISH, Secretary

SARATOGA COUNTY MEDICAL SOCIETY

The Annual Meeting of the Saratoga County Medical Society was held at the Dutch Mill, Ballston Spa, N Y, October 15, 1926, with eighteen members present. Following a delightful luncheon the business of the day was taken up.

Dr George A Wilson of Stillwater was duly elected to membership.

Dr Earl H King, President, appointed Drs A W Johnson, F Sherman and J Ledlie as the nominating committee.

Dr John Ledlie, as Treasurer, gave his report, which was accepted.

The resignation of Dr Jas T Sweetman, who served the Society as Secretary over a period of twenty years, was read and accepted.

Following the acceptance of the resignation of Dr Sweetman motion was made and seconded that he be made an honorary member of our Society.

Since Dr Ordway at Mt McGregor was unable to secure certain men to give the lectures on diseases of lung and heart, a motion was made and seconded that that course be postponed until the spring of 1927. Carried.

A motion was made and seconded that the resolution raising present dues of two dollars per annum to five dollars per annum be accepted. Carried.

The nominating committee presented the following names as candidates for officers: President, E H King, Vice-President, John Cotton, Secretary, R B Post, Treasurer, Chas Higley, Censors, Drs Fish, Gow and A W Johnson, Delegate to State Convention, Dr F Ressegue, Alternate Delegate to State Convention, T J Goodfellow. These officers were unanimously elected.

Following the business section of our meeting, an interesting paper entitled, "The End Results in Gall Bladder Surgery Dealing Especially with the Non-Calculus Group," by Dr E MacD Stanton, of Schenectady, was read.

The following doctors were present: Drs A W Johnson, Cotton, Sherman, Castree, Higley, Cornthwaite, Post, Towne, Gilmartin, Stanton, Mauro, King, Ressegue, Ledlie, Fish, Gow, Wilson, T J Goodfellow.

Adjournment

SULLIVAN COUNTY MEDICAL SOCIETY

At the annual meeting of the Sullivan County Medical Society, held on October 13, 1926, the following officers were elected for the ensuing year:

President, Dr Charles Rayevsky, Liberty, Vice-President, Dr Andrew Peters, Loomis, Secretary-Treasurer, Dr Luther C Payne, Liberty, Delegate to State Medical Society, Dr L C Payne, Liberty, Alternate Delegate, Dr R S Breakey, Monticello, Censors, Dr Howard Van Kuren, Jeffersonville, Dr John A Miller, Roscoe, Dr E Singer, Liberty, Dr C Duggan, Bethel, Dr J P Dworetzky, Liberty.

The following letter had been sent to all the members:

"Liberty, N Y, October 1, 1926

"Dear Colleague

"Please take notice that the first lecture and all the lectures and clinics have been postponed for one week. The first clinic will take place Wednesday, October 13, at 6 P M sharp, at the Maimonides Hospital in Liberty. Prior to clinic there will be the regular meeting, when the election of officers will take place, and the subject of raising the dues of the Society will be discussed.

"Clinical Lecture Course in Gastrointestinal Diseases to be given by the Gastro-enterological Department of the Long Island College Hospital Medical School to Medical Society, County of Sullivan

THE DAILY PRESS

THE CHIN AND CHARACTER

A person's chin is popularly supposed to be an indication of the degree of his will power and determination. The *New York Times* of October 31 discusses this belief and quotes from an address of Dr. Russell W. Bunting, before the recent American Dietetic Association at Atlantic City.

"A poor chin may only signify that its owner had rickets in infancy, while a strong chin may indicate not a forceful disposition but merely that as a child its owner was properly fed."

The article quotes Dr. Milo Hellman, Research Associate in Physical Anthropology in the American Museum of Natural History and lecturer on Odontology in the University of Pennsylvania.

"In most cases what is popularly known as a receding or weak chin is due to a defect in the milk which the child receives. I do not recall ever having seen a breastfed baby which developed a poor chin, while on the other hand many cases of children who were bottle-fed babies that have come under my observation have faults of the chin, a lack of jaw development. If through insufficient diet—that is, a diet which fails to furnish the right kind of body and bone building material—a child has rickets, the chin may not develop as it should."

"Chins also may project so far that they are counted as deformities. Such are due to glandular derangements. Some defect in that gland known as the pituitary body, for instance, may result in the child having abnormally large hands and feet, or a chin so large that it is unsightly. Through disease, therefore, an infant may have a trait which might be ascribed to great strength of character. Again, the large chin may be due to a malformation of the teeth, or it may be merely an inherited feature."

"From time to time have come self-styled adepts who have professed to read character by noses and chins and foreheads. The physiog-

nomists became such pests in the time of George III, for instance, that a statute was enacted threatening all professors of physiognomy with a whipping or six months in jail if they persisted in their vocation.

"As that monarch had no great strength of chin, and, in fact, the House of Hanover, on the whole, was not especially positive in its nether faces, there may have been strong personal animus in this law. Certainly George III, judging from the profiles which have come down to posterity, could not approve of the too frank criticisms of his physiognomy."

"Physiognomists recognized five leading types of chin. If the chin projected far out and was rather pointed, the owner of it was selfish, a rounded chin, but jutting, indicated benevolence, a more curved one, a passionate nature, a thin and pointed chin, a desire to love and be loved, while the receding chin denoted a cold nature, selfishness, lack of power and various other traits which did not make its bearer a social or business success."

The article also quotes "Dr. Clark Wissler of the Department of Anthropology of the American Museum also maintains that chins are not necessarily indices of character."

"There are employers," said Dr. Wissler, "who think that they are making shrewd estimates of the capabilities of persons by merely looking at them. For years we have had all kinds of experts who professed to judge of the characters of human beings by their countenances. We have had nose experts and eye experts and chin experts. The trouble with all these judgments is that when they are reduced to actual statistics they do not hold up scientifically."

Physicians, especially those who served in the Army, know how little reliance can be placed on the chin as an index of character and will power, and how futile is the so-called science of physiognomy.

CATACLYSMS OF NATURE

The cataclysms of recent months have brought home to civilized nations the helplessness of mankind in the face of the unrestrained forces of nature. Hurricanes in Florida and Cuba, and earthquakes in Armenia are still the deadly forces that they were in early historic times, with the added danger of fires in the midst of great areas of devastation from which flight is almost impossible.

Man has not penetrated the secrets of the windstorm and the earthquake. He cannot foretell either one. He can only build with steel strong enough to withstand their stresses and shocks. It is gratifying to learn that modern skyscrapers, built according to approved plans, withstood the severe tests of earthquakes that levelled all other structures.

The near approach of Mars to the earth has

ULSTER COUNTY

The Ulster County Medical Society held its regular meeting on Tuesday, October 5th, at the Sahler Sanatorium, Kingston. At the business meeting, which preceded the scientific session, Dr Raymond Crispell was appointed chairman of a Welfare Committee to canvass the resources of Ulster county in regard to public health. The following officers were elected for the coming year:

President—Dr Frederick Holcomb
Vice-Pres—Dr John F Larkin

Secretary—Dr F H Voss

Treasurer—Dr C B Van Gaasbeek.

The scientific program consisted of a paper by Dr C O Cheney, Superintendent of the Hudson River State Hospital at Poughkeepsie, on "Psycho-Therapy", and a paper by Dr Crispell on "Physiotherapy," following which demonstrations of the different baths, electrical, light and massage treatments, were given as conducted at the Sanatorium.

ALLEGANY COUNTY MEDICAL SOCIETY

The Annual Meeting of the Medical Society of the County of Allegany was held at Belmont, October 21, 1926, with the president, Dr H L Hulett in the chair. Dr H E Cooley of Wells-ville was elected president for the ensuing year, Dr N H Fuller, vice-president, Dr C R. Howen, secretary and treasurer. Drs Storner, Benedict, Connelly, Probasco and Gilray, censors, Dr C R Bowen delegate to the State Society.

SCIENTIFIC PROGRAM

Dr J W Putnam of Buffalo gave a very interesting talk on poliomyelitis and the Buffalo epidemic. There were eleven deaths out of one hundred and thirty-seven cases. Seventy per cent of the cases were under five years of age, the oldest was twenty-nine years old. Seventeen cases were of the bulbar type, fifty-six spinal, and four Landry's. The highest mortality was in the bulbar and Landry's type, the lowest in the spinal. There were instances of two cases in one family.

The serum treatment was of no use after paralysis, but might be before. Rest must be absolute. Muscles that showed some power left

must be exercised very little, or else what power they have will be lost. Convalescence was not established until all pain was gone.

Dr John Conway of Hornell gave a talk on the question "Does the cat louse convey polio?" The doctor brought out some facts to show that it does. The cat louse is the thickest during the same time of year that polio is epidemic. Several cases can be traced to the same cat. No polio is found entirely separate from cats, no polio is found in the South where there are no cat lice on the cats as the dog louse infest the cat in the South, the theory of contagion and healthy carriers does not explain the performance of polio any more than that of plague which is conveyed by rats. Cat lice will bite some people and won't others equally exposed. The paper showed work and close observation on the part of the doctor.

The Society went on record as in favor of the toxin-antitoxin campaign, and urged all doctors to use it on their private patients. A lively discussion was had in regard to the part that the State department of health and lay organizations should have in the campaign.

DINNER TO DR DOWNING

Dr Augustus S Downing, Assistant Commissioner of Education and Director of Professional Education of New York State, will be honored with a testimonial dinner in the Hotel Commodore, New York City, on the evening of Thursday, December 9th. The occasion of the dinner is the passage of the amendments to the Practice of Medicine Act last Spring and the successful inauguration of its enforcement during the summer and fall. Dr Downing has been connected with the Department of Education for over forty years and has always worked hard for medical

progress and for higher standards of medical practice. The dinner will be a recognition of the realization of the ideals for which Dr Downing was the leading champion.

The program includes Dr Livingston Farrand, President of Cornell University, toastmaster, Dr Nicholas Murray Butler, President of Columbia University, and Dr Wendell Phillips, President of the American Medical Association.

All physicians and their wives will be welcome. Tickets are \$7.50 each, and may be obtained from Dr James Pedersen, 40 East 41st Street, New York.

BOOK REVIEWS

THE THYROID GLAND By PROF CHARLES H MAYO and PROF HENRY W PLUMMER. Beaumont Foundation Annual Lecture Course IV, 1925 12mo of 83 pages St. Louis, C. V Mosby Company, 1926 Cloth, \$175

The book comprises two lectures on the thyroid gland, the first by Charles H Mayo, the second by Henry W Plummer, these lectures being the Beaumont Foundation lectures, series No 4, given under the auspices of the Wayne County Medical Society, Detroit, Michigan. The first lecture traces the history of goitre, gives a brief account of the anatomy and physiology of the thyroid gland, then takes up the various theories with reference to the etiology of goitre. The author then passes on to a discussion of the biologic chemistry of the thyroid gland leading up to the more recent discovery of thyroxin. A general survey is given of the relationship of geographic areas, environment, race, sex and age to the development of goitre. Some interesting statistical information compiled from the military draft records is included. A brief discussion is then given of the parathyroids and the metabolism in exophthalmic goitre. A brief bibliography is appended. This lecture is a very readable, interesting account of our present day conception of goitre. It is not intended to be a detailed account of any one phase of the subject.

The second lecture by Henry W Plummer gives more particularly the author's own views on the various phases of the goitre problem. There is a full account of the function of the thyroid gland, a classification of goitre which the author recommends for general use, a full and interesting account of the findings in hyperthyroid states with a careful differentiation between those found in adenoma with hyperthyroidism and in exophthalmic goitre. The author emphasizes his conception of pure hyperthyroidism as seen in toxic adenoma and the complex hyperthyroid states as found in exophthalmic goitre due, as the author believes, to a possible double secretion of the thyroid gland, namely a pure thyroxin and a possible unsaturated iodine molecule found in the thyroid secretion and produced by the excessive stimulation of the thyroid gland. At times it is somewhat difficult to separate well established facts from the author's own theories. However, in both lectures the reader can gain a very good idea of the present status of knowledge concerning the thyroid gland together with many helpful hypotheses which have many facts to support them. The book is highly recommended to all interested in endocrine diseases particularly those of the thyroid gland.

E. GOETSCH

RECENT ADVANCES IN OBSTETRICS AND GYNÆCOLOGY By ALECK W BOURNE B.A., M.B., B.Ch. (Camb), F.R.C.S. (Eng) 12mo of 344 pages, with illustrations Philadelphia, P Blakiston's Son and Company, 1926 Cloth, \$3.50

This little book takes stock of the recent advances in the field of obstetrics and gynæcology. Antepartum care, eclampsia, puerperal sepsis, placenta prævia, sterility irradiation, endometrioma and electrotherapy are particularly well covered.

Apparently progress has been made in the solution of the chemical problems of pregnancy, and clinical investigations have helped us to more definite conclusions in the management of parturition. It is stated that the treatment of prolapse has now been standardized and some space is given to illustrations which show Fothergill's method of attacking this problem. Not much mention is made of American investigators although Sampson, Rubin and Peterson are given full credit for their work. The book is valuable as a brief review. C. A. G.

COLLECTED PAPERS OF THE MAYO CLINIC AND THE MAYO FOUNDATION Edited by MRS M H MELLISH, H BURTON LOGIE, M.D., and CHARLOTTE E. EIGEN MANN, B A Volume XVII, 1925 Octavo of 1078 pages, with 252 illustrations Philadelphia and London, W B Saunders Company, 1926 Cloth, \$13.00

In this 25th series of collected papers from the Mayo Clinic the same character and excellence has been preserved as in the previously published series. It includes a wide range of diversified subjects meeting the interests of those working in the field of either general medicine or surgery. The papers of particular general interest are given in full, others of a more special nature are given in abstract together with the reference to the complete report to which those further interested can refer. Abdominal conditions with their surgical treatment are considered extensively, such conditions as ulcer of the stomach and duodenum, diseases of the liver and bile ducts, intestinal tuberculosis and carcinoma of the colon. There is a large section devoted to diseases of the genito-urinary tract, to an account of the intravenous chemotherapy in urinary infections and to surgical operations on the kidney and prostate. There are several important papers on the thyroid gland including the important thyroxin studies. Then further papers appealing more to the general medical man, such as cardiac disorders, obesity and hypertension, pernicious anemia and the like are included together with papers on syphilis, skin conditions, use of radium, treatment of tumors, bacterial studies in encephalitis, on tuberculosis and on hemolysis. To mention all the subjects would make a uselessly long list. The illustrations are abundant, clear and well chosen, adding greatly to the interest and importance of the papers. The volume is attractively compiled by the publishers and in general the book is to be recommended to both surgeons and internists wishing to familiarize themselves with present day methods and conceptions in the treatment of a long list of diseases as well as with the most recent discoveries of an original character in a considerable number of difficult and baffling conditions.

E. GOETSCH

AURICULAR FIBRILLATION By J. G. EMANUEL, B.Sc., M.D., F.R.C.P. The Ingleby Lectures, delivered at the University of Birmingham, May 6th and May 13th, 1925 Octavo of 31 pages Birmingham, Cornish Brothers, Ltd., 1926 Cloth, £0-3-6

Auricular fibrillation is one of the most frequent types of irregularity of the heart. The two lectures are a partial resume of the knowledge on auricular fibrillation.

In discussing the rate in auricular fibrillation, the author states "the case is different. An increase of rate from 70 to 100 does not mean that 30 more impulses have been generated." He does not say what the increase does mean, and from this point in the book speaks of 400 to 500 impulses arising in the auricles, and that perhaps 150 of these pass through to the ventricle. This statement without a definition makes the lectures confusing.

The author speaks of auricular fibrillation as a functional disorder, because sinus rhythm can be restored by quinine sulphate. The use of the word "functional" should be defined. The circus theory of auricular fibrillation is not explained at all, and is only mentioned in a most casual way. Throughout the lectures it is at times difficult to follow the meaning intended, and this combined with the fact that no bibliography is given renders the lectures less valuable than they might have been had more time been spent in their preparation for publication.

J. ARTHUR BUCHANAN

given rise to newspaper speculations—that the planet may have caused the earth storms and quakes (See the *New York Herald Tribune*, October 27) It is doubtful that any one would have detected anything unusual about Mars if the astronomers had not announced its approach to a distance of some forty million miles of the earth. The moon is one hundred and fifty times nearer and its influence is powerful enough to heap up the water of the ocean six feet twice

daily, but it does not produce storms or earthquakes. Much less can Mars harm the earth when its influence cannot be detected except with delicate instruments.

The earth and man have withstood numberless tests infinitely greater than those imposed by Mars and the moon. Still it must be admitted that lunacy may possibly follow too much worrying over the effects of Luna and Mars on the human mind.

ADULT INFANTILISM

A descriptive name for an old mental condition has been coined by Dr. Joseph Collins, according to a review of his new book "The Doctor Looks at Love and Life," in the *New York Times* for October 24. The pathological condition to which Dr. Collins refers is called Adult Infantilism which is defined as:

"The condition and conduct of an individual who, having reached maturity of physical development, remains infantile in his responses to the demands and obligations of life.

"Psychic infantilism in adults is characterized by the persistence in adult life of the peculiarities of the infantile psychic state. These peculiarities are weak judgment, oversuggestibility, imaginativeness, outbreaks of emotional anxiety, exaggerated sensibility, easily induced fatigue, evanescence of emotional states—particularly grief—and, in general, a trivial or playful attitude toward life. When the psychic development does not keep pace with years and with physical maturation we are justified in calling the individual an adult-infant.

"Adult-infantilism is our chief deficiency as a people, our most conspicuous national shortcoming. It is responsible for more maladjustment, more family discord and more intellectual vagrancy than any disease, derangement or other disharmony of mind and body. And the number of people thus afflicted seems to be increasing."

Many have remarked in this country of late a growing spirit of lightness, of instability and chameleon judgment. Europeans often make a point of assuring Americans that they are extremely clever and resourceful, only to smile, when the back is turned, and to pronounce us, when out of earshot, "childish."

"Take politics seriously?" No. That, according to Dr. Collins, Americans do not do. For, he notes, "to follow the trend and achievements of the country requires maturity of mind, which involves emotional maturity. That is what we lack. The happy-go-lucky attitude is so much easier. We would rather play golf or go to a football game than vote, and we cannot take the time from radios and movies to inquire into the merit of constitutional amendments. We, moral men and true, find it much easier flagrantly to break the law prohibiting the manufacture and

sale of alcohol than we do to cooperate in getting it changed or modified so that we, moral men and true, can face ourselves as such in the mirror.

"The way to make man drink is to have another man tell him he must not. Hence thousands, probably millions, who a few years ago had small inclination to take alcohol now have an urge to do so which they coddle.

"We are satisfied with ourselves and with our neighbors who agree with us and who conform their conduct to ours, but we are dissatisfied with all others and determined to make them mend their ways.

"It is the way the past generation has brought up its children, spiritually and materially, and the way the present generation is bringing up its own that is responsible for our personal and national infantilism.

"Is there any way out? No easy way. The young should be taught how to think. Thought is the expression of power in its highest and noblest form. It is the enemy of privilege, the friend of mercy, the proponent of justice."

The condition underlying adult childishness is expressed in the *Daily Press* Department of the last issue of this JOURNAL in the article on "Progress in Mental Capacity." This is a nation of children of an average mental age of fourteen years who have all the rights of choice of action that are granted to the most gifted thinkers. Eating, drinking, clothing, housing and merrymaking comprise the round of ideals of children who do not aspire to higher things because of the limitations of their mental age.

The remedy lies not in more intensive thought, for the average person cannot reason like a professor of mathematics. The cure consists in arousing obedience and respect for authority. A child or an animal may be taught to obey, but obedience is not always compatible with American independence. We are now passing through a stage of the excessive assertion of individual rights, which doctors see in the familiar statement that every person has a right to the free choice of the kind of a healer that he shall employ. The next stage will be that of a respect for the rights of others, which in the distant future may be the result of free will action based on intelligent knowledge.

BOOK REVIEWS

THE THYROID GLAND By PROF CHARLES H MAYO and PROF HENRY W PLUMMER. Beaumont Foundation Annual Lecture Course IV, 1925 12mo of 83 pages St Louis, C. V Mosby Company, 1926 Cloth, \$1.75

The book comprises two lectures on the thyroid gland, the first by Charles H Mayo, the second by Henry W Plummer, these lectures being the Beaumont Foundation lectures, series No 4, given under the auspices of the Wayne County Medical Society, Detroit, Michigan. The first lecture traces the history of goitre, gives a brief account of the anatomy and physiology of the thyroid gland, then takes up the various theories with reference to the etiology of goitre. The author then passes on to a discussion of the biologic chemistry of the thyroid gland leading up to the more recent discovery of thyroxin. A general survey is given of the relationship of geographic areas, environment, race, sex and age to the development of goitre. Some interesting statistical information compiled from the military draft records is included. A brief discussion is then given of the parathyroids and the metabolism in exophthalmic goitre. A brief bibliography is appended. This lecture is a very readable, interesting account of our present day conception of goitre. It is not intended to be a detailed account of any one phase of the subject.

The second lecture by Henry W Plummer gives more particularly the author's own views on the various phases of the goitre problem. There is a full account of the function of the thyroid gland, a classification of goitre which the author recommends for general use, a full and interesting account of the findings in hyperthyroid states with a careful differentiation between those found in adenoma with hyperthyroidism and in exophthalmic goitre. The author emphasizes his conception of pure hyperthyroidism as seen in toxic adenoma and the complex hyperthyroid states as found in exophthalmic goitre due, as the author believes, to a possible double secretion of the thyroid gland, namely a pure thyroxin and a possible unsaturated iodine molecule found in the thyroid secretion and produced by the excessive stimulation of the thyroid gland. At times it is somewhat difficult to separate well established facts from the author's own theories. However, in both lectures the reader can gain a very good idea of the present status of knowledge concerning the thyroid gland together with many helpful hypotheses which have many facts to support them. The book is highly recommended to all interested in endocrine diseases particularly those of the thyroid gland.

J. ARTHUR BUCHANAN

THE PEAKS OF MEDICAL HISTORY An outline of the Evolution of Medicine for the Use of Medical Students and Practitioners By CHARLES L. DANA, A.M., M.D., LL.D. Octavo of 105 pages, with illustrations New York, Paul B Hoeber, Inc., 1926 Cloth, \$3.00

In this work, Dr Dana has given us the best modern, brief handbook on the history of medicine. He begins with the Pro-Hippocratic Period and, in his inimitable style, presents a panoramic view of the intervening periods down to the first half of the nineteenth century.

The book consists of seven chapters, viz Introduction, The Hippocratic Period, The Alexandrian School, Galen and the Post-Galenic Period, The Renaissance of Medicine, The Period of Harvey, Physiology and Research, The Period of Jenner and Modern Medicine.

Dr Dana presents medical history by introducing to us those who have been pioneers and leaders in the evolution of the various branches of medicine.

It is our belief that the neophyte who reads this book will be inspired to delve more deeply into the progress of the healing art and that those who are students of medical history will find fascinating reading in this volume. For those who wish to make a more detailed study of the history of medicine, a very helpful and well-selected bibliography has been included.

The text has been enhanced by the incorporation of a considerable number of excellent illustrations and plates.

As an example of book-making, Mr Hoeber, with his usual good taste in make-up and typography, has produced a most attractive volume. F

ROENTGEN INTERPRETATION A manual for Students and Practitioners By GEORGE W. HOLMES, M.D., and HOWARD E. RUGGLES, M.D. Third edition, revised. Octavo of 326 pages with 226 illustrations Philadelphia and New York, Lea and Febiger, 1926 Cloth, \$5.00

This work is an outline of the general subject of Roentgen diagnosis intended chiefly for students in this specialty. The authors emphasize the importance of a good groundwork in pathology for a proper interpretation of the abnormal shadows seen on the film. This book includes chapters on the normal anatomy of the skeleton, and the more common developmental variations of the same. Appended to each chapter are references to the literature for the benefit of those who wish to pursue further study of any particular subject treated therein.

There are suggestions as to the positioning of the patient for the study of particular parts or organs. The book is up to date including such recent developments in this specialty as ventriculography and the use of iodized oil in diagnosis. The illustrations are particularly good.

As a text book on general Roentgen diagnosis, this is one of the best works in any language. The student, in order to become proficient in this specialty, must supplement this work with an extensive study of the literature and a large amount of clinical material as recommended by the authors. J G W

PERNICIOUS ANEMIA By FRANK A. EVANS M.D. 12mo of 178 pages. Baltimore, Williams and Wilkins Company, 1926 Cloth, \$2.50

This excellent monograph on Pernicious Anemia presents the most recent facts concerning this condition. The author discusses clearly accurately and instructively the findings and theories of the disease carefully differ-

entiating it from the other forms of anemia. Brief chapters logically lead from the definition, occurrence and pathological anatomy to the etiology, clinical description, diagnosis, present treatment and prognosis of this fatal condition. From the viewpoint of results of treatment at the present time, Pernicious Anemia is incurable but efforts such as the author's tend to lead to encouraging results. This work should be studied by all who care for patients. The author and publishers have given us an excellent book. HENRY M. MOSES

THE SECRETION OF THE URINE. By ARTHUR R. CUSHNY, M.A., M.D. Second edition. Octavo of 288 pages with diagrams. London and New York, Longmans, Green and Company, 1926. Cloth, \$5.50 (Monographs on Physiology)

The previous edition of this monograph is well known, and there is no apparent reason why this edition should not receive the same careful consideration. The secretion of the urine has long been a subject for investigation, and much effort has been expended on it. The way the kidney accomplishes its function has not been entirely worked out, but every phase of the subject is presented in this book, so that anyone may know and understand the present knowledge in this field.

This book is of value to student, practitioner, and investigator. The subject matter is clearly presented, and frequent illustrations add to the facility of reading. J ARTHUR BUCHANAN

THE MODERN TREATMENT OF HEMORRHOIDS By JOSEPH FRANKLIN MONTAGUE, M.D., F.A.C.S. Octavo of 296 pages, with 116 illustrations. Philadelphia and London, J. B. Lippincott Company, 1926. Cloth, \$5.00

We have had a great deal of pleasure in reading this book by Dr Montague.

The chapter on the pathology of hemorrhoids, in which there are a number of illustrations, should give the student a complete knowledge of their structure.

The fact that Dr Montague describes a number of operative procedures, the injection method and the electrical methods in the treatment of hemorrhoids shows that he does not consider any one method applicable to all cases. Attention, in this particular, may be called to the tabulation of the different treatments indicated for the cure of the various types of hemorrhoids.

There is a description entirely original with the author, of the use of radium in the treatment of hemorrhoids which deserves attention.

In this book one may find in a comprehensive form a description of every well-recognized method of treating hemorrhoids. CHARLES GOLDMAN

BRAINS OF RATS AND MEN A Survey of the Origin and Biological Significance of the Cerebral Cortex. By C. JUDSON HERRICK. 12mo of 382 pages with illustrations. Chicago, The University of Chicago Press, 1926. Cloth, \$3.00

The two species of mammals whose behavioral responses have been studied most carefully under conditions of laboratory control are rats and men. The author's discussion centers around the psychology of these two animals, as investigated by objective methods.

The reader will probably recall *An Introduction to Neurology* by the same writer. The present book is graced by the same clear presentation and interesting style of that memorable volume.

Students of psychology and neurologists will find a great deal of interest and value in *Brains of Rats and Men*. FREDERIC DAMRAU

THE POMEROY MANEUVER IN THE TREATMENT OF THE PERSISTENT OCCIPITO POSTERIOR POSITION

By HARRY ARANOW, MD, F.A.C.S., NEW YORK, N Y

BEFORE a body of this character I need no apology for the theme of this short paper. You all know that the O P position is a most eventful position and, in spite of all that has been written on the subject, the handling of a persistent O P position often taxes the ingenuity of the best obstetrician. Under the circumstances, we cannot afford to overlook a method which promises an easy and safe delivery. After an experience of over ten years of its employment in hospital and private practice, we feel that the Pomeroy Maneuver is just such a method, and, when indicated, has nothing superior at present.

To the best of our knowledge, the description of this maneuver has never been published either by Dr Pomeroy or by his associates. As a result, few obstetricians have heard of it and fewer still understand its mechanism. The unfortunate and early death of Dr Pomeroy, one of the most brilliant obstetricians of our time, makes us fear that the method may be overlooked or forgotten without being accorded a real test of its value.

WHAT IS THE POMEROY MANEUVER?

The Pomeroy Maneuver is a method employed in the correction of the *Persistent O P* position which, with a *single* introduction of the hand into, the *lower* uterine segment, flexes the head, rotates the body of the baby on its own axis *180°* and, brings the head of the baby back into the *same* oblique diagonal of the pelvis *O A*.

DESCRIPTION, FIGURE 1 R O P

The patient is prepared in the usual manner and anaesthetized. The vagina is "ironed" out. The operator uses the right hand in the R O P and the left hand in the L O P position. A long glove is of advantage but not necessary, as the hand is rarely introduced beyond the wrist. The hand and forearm is lubricated and the operator faces the leg of the patient towards which the occiput points, *i e*, the right leg in R O P,

the left leg in L O P. The hand is introduced into the vagina *thumb towards the rectum, little finger towards the symphysis pubis*.

As soon as the hand is introduced into the vagina, the operator by turning his body away from the patient and further pronating his forearm, brings the palm of his hand in contact with the occiput. The hand is then gently *insinuated past* the occiput until the fingers rest on the baby's shoulders. To do that the operator will have to bend his knees sufficiently to bring his straight

Fig 1 R O P

* Read at the Annual Meeting of the Medical Society of the State of New York, at New York, March 31, 1926

Fig 2, R O P

outstretched arm, elbow up, in line with the pelvic inlet. The operator next brings his thumb in front of the baby's posterior shoulder.

In passing the head the operator should do two things: (1) Feel the ear to make the diagnosis absolutely positive. (2) Flex the head. This releases the head from the anterior wall of the pelvis, disengages the head sufficiently for the coming rotation and makes the reaching of the baby's shoulders easier.

The head must not be displaced unnecessarily. The reason for this is self-evident, and is to avoid causing a prolapse of the cord.

The operator now has the baby's neck and occiput in front of his palm, his thumb and index finger grasp the baby's posterior shoulder, while the rest of his fingers are spread over the baby's back. (See Figures 2 and 3.)

FIGURE 3 END OF MANEUVER L O A.

By supinating his forearm, rotating his arm outwards and, at the same time bringing his body around to face the patient, the operator rotates the baby's body 180°, i. e., from R O P to L O A., or from L O P to R O A. This rotation of 180° avoids the possibility of a recurrence or springing back to the original position, and, it has the added advantage of bringing the molded or partly molded head into the *normal, molded, oblique* diameter of the pelvis. In other words, the head is brought into the same diameter of the pelvis that it was in originally,

only now the occiput is anterior. Experience has shown this to be a real advantage.

This maneuver must be done gently and without haste. The grasp of the baby is firm. The rotation being in the long axis of the baby, is always easy and requires no outside assistance.

Before removing his hand, the operator brings the flexed head down to the pelvis, assisted by pressure from the outside hand.

This completes the maneuver.

DELIVERY

The further course of treatment will depend on a fresh survey of the mother and baby, their condition, and, their relation in the new position. In a great many of these cases the pelvis is relatively large and the baby relatively small (Kerr's Operative Midwifery, page 26, Volkmann's Sammel Klin., Vortrage LX, 1892). As soon as the head is rotated it sinks deeply into, sometimes through the pelvic inlet.

These cases can be delivered with forceps immediately and the patient saved further pain and the disappointment of finding herself conscious and *undelivered*. If left to nature, they deliver themselves in a very short time, the resistance of the perineum having been removed by the "ironing" out process. In the average case, if there are no contra-indications, the mother is given a rest by a dose of morphine and the case left to nature. When the head is on the perineum, they may be delivered with forceps and saved further exhaustion.

Fig. 3—L O A.

WHAT DOES THE POMEROY MANEUVER ACCOMPLISH?

It accomplishes the elimination of the O P position as a cause of dystocia. The case has been converted to an O A position and nothing has been done to interfere with any future treatment of the case that may be found necessary.

WHAT ARE ITS DANGERS?

Our experience makes us feel that with ordinary care the danger is practically nil. It should be attended with no more risk to the mother than an ordinary examination under anaesthesia. We can readily see that there is a possibility of causing prolapse of the cord. We have not had this accident as yet. Unnecessary displacement of the head should be avoided. Version has often been advocated as the best treatment for high persistent O P. Should the cord prolapse one can perform a version without removing his hand from the vagina.

WHAT ARE ITS ADVANTAGES?

1. Its comparative safety

The hand does not go beyond the lower uterine segment as it does in version.

The whole operation is performed with a single introduction of the hand.

There is no danger of rupturing the uterus.

The baby's head is not twisted on its body as it is in all maneuvers where the head is rotated either manually or by forceps. This twisting of the neck may do considerable damage to the baby.

It does less damage to the maternal parts than rotation by instruments. (It really does *no* damage to the maternal parts.)

2. It is positive in its results

The body of the baby having been rotated, the head remains in the position it is placed. In all maneuvers in which the head is rotated, it is usually hard to hold the head in place long enough to apply the forceps.

3. It is easy of performance

Once the various steps are grasped, the performance is easy. It can be done in less than a minute. My associates and interns have performed it without difficulty. It does not require the technical, obstetrical skill necessary for the performance of a version, the application and use of a Kielland forceps, the performance of a Scanzoni maneuver.

It is mechanically much easier, technically more finished and, requires less displacement of the head than "pulling on the anterior shoulder, and rotating the body with the aid of outside hand" a method suggested by some authorities.

4. It is truly conservative.

Nothing is done beyond removing the cause of the dystocia. It eliminates the O P as a cause of dystocia without interrupting the natural process of labor or interfering with any future treat-

ment that may be found necessary. No serious operation has been undertaken.

Any good physician, with ordinary care, can perform this maneuver and leave the rest to nature, feeling sure that he has done nothing that will complicate the case, and that, should consultation be necessary he has done nothing that will make it more difficult for the consultant.

WHAT ARE THE INDICATIONS FOR ITS USE?

Without going into the details of the treatment of O P positions we want to emphasize one fact, true in all operative deliveries, but especially pertinent in the O P positions. No interference until the os is fully dilated. The great majority of the O P positions terminate as O A spontaneously. In order to rotate anteriorly the occiput must strike the pelvic floor. It is the pelvic floor that directs the occiput "downwards, forwards and inwards." No case can be considered *persistent O P* until the occiput has been given a fair chance to strike the pelvic floor.

For the purpose of treatment the *persistent O P* positions may be divided into three main groups.

1. Those in which the head remains high, *i. e.*, above or at the inlet of the pelvis.

2. Those within the pelvic inlet.

3. Those cases in which the head is within the pelvis or on the perineum.

The first class is by far the most serious and the most difficult to handle, and, it is in this class of cases that the Pomeroy Maneuver is a method par excellence. To those who still feel that version should not be performed without definite indications, this maneuver should appeal as being both safer and easier. Those obstetricians who are in the habit of using, in this class of cases, a method which rotates the head, whether it be the Scanzoni Maneuver, the Kielland forceps, or manual rotation, will find this method, easier, safer, and far more certain in its results. Those who are in the habit of pulling on the anterior shoulder, will find this maneuver easier and more "finished."

In the second class of cases the Pomeroy Maneuver is indicated only when the head is easily displaced upwards, whether it be because lack of engagement or the comparative roominess of the pelvic inlet. Where the head is firmly engaged, we prefer forceps rotation of the head. Occasionally, in this type of case, we have succeeded with the Pomeroy after an unsuccessful attempt at correction by manual and forceps rotation (Case 5).

The Pomeroy Maneuver is not indicated in the third class of cases, with some very rare exceptions.

REPORTS OF TYPICAL CASES

We have selected the records of a few typical cases to show the indications, for the Pomeroy

Fig 2, R. O. P

outstretched arm, elbow up, in line with the pelvic inlet. The operator next brings his thumb in front of the baby's posterior shoulder.

In passing the head the operator should do two things: (1) Feel the ear to make the diagnosis absolutely positive. (2) Flex the head. This releases the head from the anterior wall of the pelvis, disengages the head sufficiently for the coming rotation and, makes the reaching of the baby's shoulders easier.

The head must not be displaced unnecessarily. The reason for this is self-evident, and is to avoid causing a prolapse of the cord.

The operator now has the baby's neck and occiput in front of his palm, his thumb and index finger grasp the baby's posterior shoulder, while the rest of his fingers are spread over the baby's back. (See Figures 2 and 3)

FIGURE 3 END OF MANEUVER L. O. A.

By supinating his forearm, rotating his arm outwards and, at the same time bringing his body around to face the patient, the operator rotates the baby's body 180°, i. e., from R. O. P. to L. O. A., or from L. O. P. to R. O. A. This rotation of 180° avoids the possibility of a recurrence or springing back to the original position, and, it has the added advantage of bringing the molded or partly molded head into the *original, molded*, oblique diameter of the pelvis. In other words, the head is brought into the same diameter of the pelvis that it was in originally,

only now the occiput is anterior. Experience has shown this to be a real advantage.

This maneuver must be done gently and without haste. The grasp of the baby is firm. The rotation being in the long axis of the baby, is always easy and requires no outside assistance.

Before removing his hand, the operator brings the flexed head down to the pelvis, assisted by pressure from the outside hand.

This completes the maneuver.

DELIVERY

The further course of treatment will depend on a fresh survey of the mother and baby, their condition, and, their relation in the new position. In a great many of these cases the pelvis is relatively large and the baby relatively small (Kerr's Operative Midwifery, page 26, Volkmanns Sammel Klin., Vortrage LX, 1892). As soon as the head is rotated it sinks deeply into, sometimes through the pelvic inlet.

These cases can be delivered with forceps immediately and the patient saved further pain and the disappointment of finding herself conscious and *undelivered*. If left to nature, they deliver themselves in a very short time, the resistance of the perineum having been removed by the "ironing" out process. In the average case, if there are no contra-indications, the mother is given a rest by a dose of morphine and the case left to nature. When the head is on the perineum, they may be delivered with forceps and saved further exhaustion.

Fig. 3—L. O. A.

and so easily, that the physician assisting me, never realized I had done anything out of the ordinary, and was astonished when I told him that I had rotated the baby's body manually. He was convinced only after an internal re-examination. Baby delivered with forceps L O A, easily and without any damage to either baby or mother.

Summary Persistent R O P Occiput in hollow of sacrum Attempts at manual and for-

ceps rotation of the head not satisfactory Pomeroy Rotation followed by easy forceps delivery

CONCLUSION

In conclusion, let me repeat, that after an extensive experience of over ten years, we find the Pomeroy maneuver an excellent, safe and easy method of treatment of cases of persistent occipito posterior, high in the pelvis, and we earnestly recommend it to your consideration for trial.

APICAL PNEUMONIA—REPORT OF SEVENTEEN CASES

By GORDON S. BUTTORFF, MD, LOUISVILLE, KY

From the Department of Medicine of the University of Louisville.

ALTHOUGH the literature abounds with data on almost every phase of pneumonia, there has been comparatively little written concerning the prognosis in those cases in which the pathology is located chiefly in one or both apices. Of course it is generally conceded that the prognosis in pneumonia is less affected by the location and amount of pathology than by the degree of toxic absorption. However, the belief is current that other things being equal, pneumonic involvement of the apex of the lung offers a higher mortality than is the case when the pathology is located elsewhere in the lung.

According to Osler,¹ the cases of apical pneumonia are most apt to be accompanied by cerebral symptoms. Quoting him, "It is stated that apex pneumonia is more often accompanied by severe delirium. Occasionally the cerebral symptoms occur immediately after the crisis. Mental disturbance may persist during and after convalescence, and in a few instances delusional insanity follows, the outlook in which is favorable."

R. C. Davis² feels that involvement of the right upper lobe, either alone or following other involvement, is serious. It has been his experience that these cases are usually delirious and hard to restrain. He has further observed that when pneumococcic meningitis follows pneumonia, the area of lung involvement is the right upper lobe. Hence he concludes that the mortality rate of right upper lobe involvement is very high. That pneumococcic meningitis is usually secondary to lobal pneumonia of the right upper lobe is, clinically speaking, contradictory to Osler, who says, "It usually comes on at the height of the fever, and in the majority of the cases is not recognized unless the base is involved, which is not common."

Commenting on the location of the pathology, Lissner,³ states that, "Primary infection

of either upper lobe is not as frequent as was previously supposed, right middle lobe involvement is not common."

In a report of 225 cases of pneumonia, Owen⁴ says in part, "Of the lobar cases, five were apical (four right side), and of these, four were associated with severe delirium, one was fatal."

In reviewing 339 cases of pneumonia at the Louisville City Hospital from October, 1923, to June, 1925, our cases of apical pneumonia actually offered a lower mortality than those cases in which the pathology is located elsewhere in the lung.

Our cases have not been considered from the standpoint of signs and symptoms. It might here be added that none of our apical cases showed marked delirium or cerebral symptoms, nor were any of this type complicated by pneumococcic meningitis.

Our cases were not typed and therefore, no effort was made to determine etiology. Many of our cases were admitted practically moribund, and the work on them was insufficient to determine from the record just which lobe was involved, other than "pathology at the bases," etc. For this reason I have merely classified my pathology as, at the apex, at the bases, or combined, in which case apex and base were involved together or with the middle lobe.

This paper is not offered with the idea or expectation of revolutionizing our beliefs about the severity of apical pneumonia—too many uncontrolled factors enter into these cases for that—but it is thought that perhaps in the course of time, if the cases in other hospitals are reviewed with this aspect in mind, it might be found that pneumonia involving the apex of the lung is no more to be feared than cases with the pathology elsewhere.

Maneuver, and what is equally as important, the proper kind of after-treatment. An improperly selected high forceps application is no more justified after a Pomeroy than at any other time, but it may mar the result of a well-selected, perfectly performed maneuver.

Case 1—Mrs T F, age 22, nat U S, married 19 mos, Para 1 family, previous and menstrual history unimportant. Last period, April 6, 1916. Date of expected confinement, Feb 13, 1917. Pelvic measurements, normal. Pregnancy, normal.

Patient went into labor early in the morning of Feb 9, 1917. Admitted to Lebanon Hospital at 7 A M, Feb 9, 1917, in active labor. Throughout the day patient had characteristic, irregular, ineffectual pains. Given morphine in sufficient doses to give patient some rest. At 9 A. M, Feb 10, 1917, patient fully dilated, head unengaged in R O P position. Membranes ruptured. Active pains and no progress after five hours. Patient taken to operating room at 2 P M. Pomeroy Maneuver performed and patient allowed to come out of a very short anaesthesia. Baby born spontaneously at 2 35 P M.

Summary Patient made no progress with five hours of good pains, but delivered herself within a half an hour after a Pomeroy.

Case 2—Mrs A S, age 25, nat U S, married 6 months, Para 1 family, previous and menstrual history unimportant. Last period April 28, 1924. Date of expected confinement, Feb 5, 1925. Pelvic measurements Sp 24, Cr 28 Tr 33 Ext Conj 20 R O 23 L O 23 Bisischial 11 Post sag good Diag Conj ample.

Went into labor on the morning of Jan 25, 1925. Admitted to Nursery & Child's Hosp. Fully dilated at 4 P M, Jan 25, 1925. Head high, R O P. Roomy pelvis. No progress at 9 P M. Taken to delivery room and Pomeroy Maneuver performed. Head sank down into pelvis at end of maneuver. Delivered with forceps easily and without any apparent damage to either mother or child.

Summary Persistent O P in justo major pelvis. Pomeroy rotation followed by immediate forceps delivery.

Case 3—B S, age 26, nat Russia, Para 11, family, personal, and menstrual history unimportant. Previous labor, difficult.

Called to see the case in consultation with Dr H. Patient has been in labor for 36 hours. Full dilatation for hours with no progress. Admitted to Lebanon Hospital at about 3 A M, Feb 23, 1924. Pomeroy rotation. Head remained high after maneuver. Attempt to engage with forceps unsuccessful. Patient allowed to come out and given $\frac{1}{4}$ gr of morphine by hypodermic. At 9 50 A M, Feb 24, 1924, head on perineum. Delivered with low forceps. Still-born.

Summary Persistent O P. Contracted pelvis. Pomeroy rotation. Head high. Attempt to engage the head with high forceps was poor judgment on my part. When left to nature, head came down on perineum in a few hours.

Case 4—Mrs J F, age 27, nat. U S, married 10 months. Family, previous, and menstrual history, unimportant. Date of last menstruation, Nov 20, 1924. Date of expected confinement, Aug 27, 1925.

Measurements Sp 22, Cr 27, Tr 31, Ext Conj 17, R O 23, L O 21, Bis 10, Post Sag good, Diag Conj 12.

Pelvis, poor. Funnel type with Naegele characteristics. Pregnancy uneventful except that the head remained in R. O P position in spite of postural treatment and that the head remained high above the inlet and could not be brought down. Consultation with another obstetrician suggested and accepted. Consultant advised waiting for a "test of labor." Patient had irregular pains from Aug 30 to Sept 7, when she went into active labor. Readmitted to the Nursery & Child's Hosp on Sept 7, 1925, Labor Day. When I arrived from my country home several hours later, patient was in active labor, os almost fully dilated, membranes ruptured for some time, probably for days, fetal heart rapid and poor.

Taken to delivery room and Pomeroy rotation performed. Fetal heart rapid and irregular making immediate delivery urgent. When gentle attempt to deliver with forceps failed, a podalic version was done and baby delivered without difficulty.

Summary Persistent O P in prolonged dry labor. Pomeroy maneuver had to be followed by an immediate delivery in the interest of the baby. The O P position was no longer a factor, and the case was handled on its merits, a gentle attempt with forceps followed by a version.

Case 5—Mrs J S, age 31, schoolteacher, nat U S, married four years, Para 1 family, previous and menstrual history, unimportant. Last menstruation, April 30, 1925. Date of expected confinement, February 7, 1926. Pregnancy normal. Postural attempts at correction of the O P position not successful.

Patient went into labor on Feb 16, 1926. Admitted to the Hunts Point Hospital. Characteristic, irregular, ineffectual, labor pains. Patient given morphine P R. N. Fully dilated at 7 A M, Feb 17, 1926, head well engaged. At 10 A M the occiput in the hollow of the sacrum. Taken to delivery room and prepared. Pelvis roomy. Manual rotation seeming impossible, the Scanlon maneuver was tried. In spite of using Dr Seides modification, a proper bi-parietal application with the second forceps seemed impossible, the head turned back a little as soon as the first forceps was loosened. Accordingly, I removed the forceps, pushed the head up, and performed a Pomeroy rotation. This was done so quickly

and so easily, that the physician assisting me, never realized I had done anything out of the ordinary, and was astonished when I told him that I had rotated the baby's body manually. He was convinced only after an internal re-examination. Baby delivered with forceps L O A., easily and without any damage to either baby or mother.

Summary Persistent R O P Occiput in hollow of sacrum Attempts at manual and for-

ceps rotation of the head not satisfactory Pomeroy Rotation followed by easy forceps delivery

CONCLUSION

In conclusion, let me repeat, that after an extensive experience of over ten years, we find the Pomeroy maneuver an excellent, safe and easy method of treatment of cases of persistent occipito posterior, high in the pelvis, and we earnestly recommend it to your consideration for trial.

APICAL PNEUMONIA—REPORT OF SEVENTEEN CASES

By GORDON S. BUTTORFF, MD, LOUISVILLE, KY

From the Department of Medicine of the University of Louisville.

ALTHOUGH the literature abounds with data on almost every phase of pneumonia, there has been comparatively little written concerning the prognosis in those cases in which the pathology is located chiefly in one or both apices. Of course it is generally conceded that the prognosis in pneumonia is less affected by the location and amount of pathology than by the degree of toxic absorption. However, the belief is current that other things being equal, pneumonic involvement of the apex of the lung offers a higher mortality than is the case when the pathology is located elsewhere in the lung.

According to Osler,¹ the cases of apical pneumonia are most apt to be accompanied by cerebral symptoms. Quoting him, "It is stated that apex pneumonia is more often accompanied by severe delirium. Occasionally the cerebral symptoms occur immediately after the crisis. Mental disturbance may persist during and after convalescence, and in a few instances delusional insanity follows, the outlook in which is favorable."

R. C. Davis² feels that involvement of the right upper lobe, either alone or following other involvement, is serious. It has been his experience that these cases are usually delirious and hard to restrain. He has further observed that when pneumococcic meningitis follows pneumonia, the area of lung involvement is the right upper lobe. Hence he concludes that the mortality rate of right upper lobe involvement is very high. That pneumococcic meningitis is usually secondary to lobal pneumonia of the right upper lobe is, clinically speaking, contradictory to Osler, who says, "It usually comes on at the height of the fever, and in the majority of the cases is not recognized unless the base is involved, which is not common."

Commenting on the location of the pathology, Lissner,³ states that, "Primary infection

of either upper lobe is not as frequent as was previously supposed, right middle lobe involvement is not common."

In a report of 225 cases of pneumonia, Owen⁴ says in part, "Of the lobar cases, five were apical (four right side), and of these, four were associated with severe delirium, one was fatal."

In reviewing 339 cases of pneumonia at the Louisville City Hospital from October, 1923, to June, 1925, our cases of apical pneumonia actually offered a lower mortality than those cases in which the pathology is located elsewhere in the lung.

Our cases have not been considered from the standpoint of signs and symptoms. It might here be added that none of our apical cases showed marked delirium or cerebral symptoms, nor were any of this type complicated by pneumococcic meningitis.

Our cases were not typed and therefore, no effort was made to determine etiology. Many of our cases were admitted practically moribund, and the work on them was insufficient to determine from the record just which lobe was involved, other than "pathology at the bases," etc. For this reason I have merely classified my pathology as, at the apex, at the bases, or combined, in which case apex and base were involved together or with the middle lobe.

This paper is not offered with the idea or expectation of revolutionizing our beliefs about the severity of apical pneumonia—too many uncontrolled factors enter into these cases for that—but it is thought that perhaps in the course of time, if the cases in other hospitals are reviewed with this aspect in mind, it might be found that pneumonia involving the apex of the lung is no more to be feared than cases with the pathology elsewhere.

SUMMARY OF CASES

Type Case	LOBAR PNEUMONIA			Total	BRONCHO PNEUMONIA			Total
	Apex	Location of Pathology Combined	Elsewhere		Apex	Location of Pathology Combined	Elsewhere	
	17	14	143	174	9	49	107	165
Average Age	31.9	40.3	38.2		25.5	27.7	40.5	
Age Limits	8-58	1-75	1 mo-95		11/3-60	2 mo-80	3 mo-95	
Male	11	10	100	121	4	29	67	100
Female	6	4	43	53	5	20	40	65
White	8	6	82	96	5	25	54	83
Colored	9	8	61	78	4	25	53	82
Recovered	11	4	74	89	7	18	48	73
Died	6	10	69	85	2	31	59	92
Post-Mortem	2	8	15	25	0	16	24	40
Per Cent Mortality	35.3%	51.6%	48%	48.8%	22.2%	58.6%	55.1%	55.7%

Summary—This report includes 174 cases of lobar pneumonia and 165 cases of broncho pneumonia, a total of 339 cases. Total number of deaths, 177, with a mortality 52.2 per cent. Of 174 cases of lobar pneumonia, the apex alone was involved in 17, the pathology was combined apex and base in 14 and at the bases in 143. The average age was 37.7 with a range from 1-85 years. Total deaths in lobar pneumonia, 85, with a mortality of 48.8 per cent. Of the cases of broncho pneumonia, totaling 165, 9 were at the apex, 49 combined and 107 elsewhere, 92 died, giving a mortality of 55.7 per cent. The average age was 29, ranging from one month to 95 years.

19.7 per cent, or 67 cases, were terminal infections with an average age of 63.5 years and a range of 19 to 95 years.

Sixty-five, or 19.1 per cent, of our cases were necropsied, 14.3 per cent being among the lobar, 24.2 per cent among the broncho pneumonia, 34.8 per cent of the cases were in females, 53 lobar and 65 broncho, a total of 118, of which 59 died, yielding a mortality of 50 per cent, 65.2 per cent were among males, 12 lobar and 100 broncho, totaling 221 with 118 deaths with a mortality of 53.3 per cent. Among the white patients, 96 were lobar and 83 broncho, totaling 179, with 103 deaths and a mortality of 57.5 per cent. Seventy-eight lobar and 82 broncho, 160 in all, with 76 deaths or a 47.5 per cent mortality, occurred among the negroes.

Comment—None of our states of apical pneumonia developed cerebral symptoms. One of our cases developed a pneumococcic meningitis, the pathology in the lung being at the right base and entire left lung. In this series of cases, involvement of one or both apices alone gave a mortality of 35.3 per cent in lobar and 22.2 per cent in broncho, as contrasted with a mortality of 48 per cent in lobar with-

out any apex involvement and 54.2 per cent in broncho pneumonia.

It would seem that pneumonia involving the apices is a little more common and perhaps less serious than is often supposed.

The mortality rate of all of our cases is far too high, but many of them were brought in almost moribund, while in others the disturbance of moving the patients into the hospital late in the disease may have been the determining factor.

The colors were almost equally divided, although the mortality was greater among the whites.

The males outnumbered the females almost two to one, but the mortality ratio was about equal.

As the sputa of our cases were not typed, etiology had to be omitted and this might perhaps have had an important bearing on our mortality in the apical cases as contrasted with those having their pathology elsewhere.

CONCLUSIONS

1. Apical pneumonia is more common and less serious than often supposed.
2. Our cases of apical pneumonia showed no tendency toward cerebral manifestations nor pneumococcic meningitis.
3. We believe that if the pneumonias in other hospitals are reviewed probably the findings will simulate ours.

MORE RECENT STUDIES UPON THE ETIOLOGY OF POSTOPERATIVE PNEUMONITIS*

By ALLEN O WHIPPLE, M.D., NEW YORK CITY

From the Department of Surgery, Columbia University, and the Surgical Service of the Presbyterian Hospital.

THERE is no more complicated nor puzzling problem in medicine today than the study of the pathogenesis of respiratory infections. The morbidity and mortality of these diseases heads the list in our public health statistics and comes close to every one of us personally in the home, the school, the city and the country. The common cold especially in our artificial and crowded city life is the usual forerunner of the more serious respiratory diseases and in itself is a problem that has baffled all investigation.

The failure to solve this problem of respiratory infections is due to many variable factors, variables such as the association of different exciting organisms, their changing virulence, the degree of susceptibility or immunity of the host, the variations in the crowding of the populace in buildings and conveyances, the variable weather and seasonal conditions. The approaching peak of the eight-year influenza curve is a dreadful thought, a prospect no more comforting than in 1918.

The problem of post-operative respiratory infections is for the same reasons as complicated and as unsolved as in non-surgical conditions. In some ways more complicated because in addition to the above variables there are factors peculiar to surgical procedures and to altered anatomical relations. To attempt to explain all these post-operative respiratory infections on one basis or to expect to eliminate them by removing a single etiology is illogical and entirely futile.

The studies of a number of investigators in the past ten years have pointed out three fairly well defined pathological processes in the production of post-operative pulmonary complications. The first of these is the aspiration of infected secretions into the bronchial tree during a general anaesthesia with the disappearance of the cough reflex. The second is the factor of pulmonary infection due to the emboli, sterile or septic, coming from a venous thrombus. The third factor is a variable degree of atelectasis. The great majority of so-called post-operative pneumonias are associated with one or the other of these factors, and are lobular in type. These lesions differ from the ordinary lobar pneumonias in their onset, course and termination, and are for this reason frequently overlooked under the term "post-operative reaction." But they nevertheless delay the immediate recovery and in abdominal cases, because of the associated cough, jeopardize the wound healing. There are in addition a certain number of clear cut lobar pneumonias of

the type seen in medical practice due to *Pneumococcus* I, II or III, and the pneumonias associated with septicemia and pyemia.

The mistake that has been made in the discussions of the several investigators is the attempt to explain these lesions on one basis alone, without considering the many other associated factors.

In regard to the first pathological process, the aspiration of the infecting organism Höelsche (1) in 1898 was the first to prove this experimentally. He used gentian violet in the pharynx of dogs and guinea pigs under surgical anaesthesia, as an indicator, and found the dye in the smallest bronchi of six of twelve dogs, in three the dye had not descended beyond the trachea, in two dogs it had not passed beyond the larynx. In 1920, Mullen and Ryder (2) reported experiments on two rabbits in which they had injected 1 c.c. of emulsion of human tubercle bacillus into the noses of the rabbits without anaesthesia. In each case the animal developed localized lesions in the lung. Corper (3) taking this suggestion, reported in 1922 a series of experiments on 9 dogs in which he had allowed 10 c.c. of a suspension of dead human tubercle bacilli to be instilled into the mouth of the anaesthetized dog with the animal on his side. Definite pulmonary lesions were produced in all the animals, on the side on which the animal lay. Myerson (4) in 1924, published a report of bronchoscopies which were carried out in 100 patients following tonsillectomy under light anaesthesia. Of seventy-eight that did not cough during the tonsillectomy bloody mucus was present in the tracheo-bronchial tract of seventy-two, whereas in eighteen of the twenty-two patients retaining the cough reflex, no blood or mucus was found below the larynx. Lemon (5) in 1925, read a paper at the meeting of the American Association for Thoracic Surgery, an aspiration of foreign material during anaesthesia. By means of indicators such as gentian violet, India ink, 20 per cent suspension of bismuth, and lipiodol, experiments were conducted on dogs under ether anaesthesia. An attempt was made, both in the administration of the anaesthesia and in the posture of the animal to simulate closely the conditions in clinical practice. He used a variable amount of the indicator, 20 to 40 c.c. allowing it to drip slowly into the cheek of the animal by separating the lips and drawing them away from the teeth. The animals were kept under surgical anaesthesia for periods varying from twenty minutes to an hour. According to his report, the risk of extensive aspiration of mucus from the mouth into the lower respiratory passages was increased by placing

* Read at the Annual Meeting of the Medical Society of the State of New York, at New York March 31, 1926.

the subject on an inclined plane in the head-up position. The risk decreased as the plane was reversed and to the vanishing point when a full Trendelenburg position was reached. In all other postures the dogs aspirated into the lower air passages or into the depth of the lungs, especially the lower lobes, regardless of whether the head was in a straight line with muzzle up or with the head to one side. The danger of aspiration was increased when the animal struggled under light anaesthesia, or when breathing was stertorous or if the animal swallowed or vomited. Lemon also used broth cultures of *Bacillus prodigiosus* as an indicator in 5 to 10 c.c. amounts. He does not state the number of animals in this group but says that positive cultures were found at the bifurcation and in the depths of the bronchi, and from the lung tissue itself.

Because of the large amount of indicator used in these experiments we felt that the conditions did not represent normal anaesthesia in that they were artificial and that the aspiration simulated rather than seen in patients with vomitus present in the pharynx during surgical anaesthesia.

Dr Meleny (6) of our Surgical Department undertook a similar set of experiments on rabbits using 1 c.c. amounts of lipiodol and 0.3-1 c.c. of bacterial cultures. Rabbits were tied to a board and the body tipped at an angle of 45°. In each series one rabbit was held with head up 30 minutes without anaesthesia, one with head up with deep anaesthesia for 30 minutes, and the third with head down with deep anaesthesia for 30 minutes. His results were by no means as constant as those reported by Lemon. They were as follows:

1 Lipiodol entered the lungs of the rabbit with head up with anaesthesia but did not enter the lung in the others.

2 1 c.c. of 24 hour culture of *Pneumococcus* I introduced into the mouth of non-immunized rabbits produced pneumonia, empyema, pericarditis and septicemia in all three, irrespective of the position or the anaesthetic.

3 No pneumonia was produced in immunized rabbits with *Pneumococcus* I nor in normal rabbits with *Pneumococcus* IV, irrespective of their position or the anaesthetic.

4 B. Welchii in concentrated suspension introduced into the mouth entered the trachea and lungs of anaesthetized animals, those with head lowered as well or better than those with head raised, but did not enter the trachea or lungs of unanaesthetized rabbits.

CONCLUSIONS

1 Gravity may be a factor in permitting heavy fluids like lipiodol to enter the lungs from the throat in anaesthetized rabbits with head raised or in preventing its entrance if head is lowered.

2 The factor of gravity is negligible with

lighter fluids and does not prevent their entrance under anaesthesia with head lowered.

3 Anaesthesia is conducive to the entrance of fluids from the mouth into the trachea and lungs of rabbits irrespective of the factor of gravity.

4 *Pneumococci* entering the lungs of rabbits under anaesthesia does not always produce pneumonia.

Soper (7) of Saranac has obtained results similar to those of Corper and Lemon. Working with rabbits and using live tubercle bacilli, he has been able to produce tuberculous lesions in the right lung by instilling an emulsion of the bacilli into the nostril while the animal was lying on the right side under anaesthesia. These experimental studies, as well as clinical experiments, establish the fact that under general anaesthesia aspiration can and does occur, but it must be remembered that the production of an inflammatory process depends upon the virulence of the organism, susceptibility of the patient, the presence of a damaged area of lung-tissue and the ability or disability of the subject to expel the contaminating material. The remarkable fact is that pneumonia does not occur more frequently following general anaesthesia.

The second pathologic process. Infarction of the lung.

Cutler (8) has emphasized this factor in a number of brilliant papers. In his last report of 63 post-operative pulmonary complications he classified thirty-two, or one half, as belonging to this embolic group. Many of the cases which he describes occurred shortly after operation and their signs and X-ray findings were very similar to the group which we consider at the Presbyterian Clinic to be Group IV Pneumonia infections. We base our classification on serological tests which were published in our report (9) in 1918. Undoubtedly a few of the early pneumonia cases and many of the late cases are embolic in nature but Cutler does not give due credit to the factor of descending infection and to the organisms present in aspirated secretions that become active in the lung tissue damaged by infection. Colp and Louria (10) have recently carried out some very interesting experiments in our Surgical Laboratory which are of interest from Cutler's standpoint. They injected metallic mercury into the jugular vein of dogs as an indicator for studying the action of the lungs and diaphragm under the fluoroscope with and without celiotomy wounds. In an astonishingly uniform manner the mercury appeared to concentrate in the pulmonary artery branches of the lower lobes, and in some of the X-ray films more particularly in the right lower lobe. This occurred in animals with and without anaesthesia, with and without celiotomy. The anatomical or physiological reason for this is as yet undetermined.

In the late pulmonary complications there are undoubtedly many cases of embolism causing in-

fection with and without the production of a pneumonitis. These cases merge into the very serious group of cases, fortunately few, that die suddenly with pulmonary embolism.

The third pathological process Atelectasis

Following Scrimger's (11) report from Montreal the attention of clinicians was called to the condition of massive lung collapse, first described by Pasteur (12) in 1908. It soon became evident that this condition was overlooked in the absence of careful examination of the cardiac area. By percussion and X-ray the shift of the heart and mediastinum to the side of the collapsed lung is strikingly demonstrated in this condition. Since 1921 we have diagnosed 12 cases at the Presbyterian clinic as a post-operative complication. But we have looked for this condition carefully and during this same period have had no marked decrease in our pneumonitis cases. In only two of our patients coming to autopsy has this condition of partial lung collapse been found. In view of our experience I feel that the conclusions of Elwyn (13) from the Mt Sinai Clinic are open to criticism for he considers practically all so-called post-operative pneumonias occurring after a celiotomy as having a preceding partial or complete atelectasis of a lobe of the lung. He believes that the collapse or atelectasis is brought about by a reflex stimulus from the gastro intestinal tract by way of the vagus, resulting in a constriction of all the bronchioles of a portion of the lung.

Colp and Louria (10) in the course of their investigation of mercury injections of the pulmonary arteries observed that very definite mobilization of the diaphragm occurs when traction is applied to the upper abdominal viscera, especially the liver, stomach and spleen. A similar result but less striking occurs when heavy traction is applied to an upper abdominal wound. With the stoppage of movement in one leaf or the other of the diaphragm or both, there occurs rather promptly a compensatory increase in the action of the intercostal muscles with an increase in the lateral expansion of the lung. With the release of traction on the viscera or traction on the upper abdominal wound the diaphragm fairly promptly resumes its normal excursion.

These observations are of great interest for they corroborate clinical observations that post-operative lung complications are far more common following celiotomy and most common following upper abdominal operations. They further lend weight to the theory that there occurs a variable amount of atelectoasis in the lower lobes of the lung resulting in a pneumonitis. Elwyn (13) acknowledges the role of descending infection when he states "Evidence for the assumption that the infection extends from the bronchi into the atelectatic area of lung may be found in the clinical characteristics of post-operative pneumonia." It

should be emphasized that he considers atelectasis as the first step in the production of post-operative pneumonitis.

It must be evident to one who has studied this problem with an open mind that no one of these three pathological processes can be considered the sole etiological factor. The more recent studies of Myerson, Lemon, Soper and Meleney show that potentially infectious material passes down the bronchial tree in a fairly large number of individuals under general anesthesia. The theory of embolism and of partial atelectasis as first steps in the production of pneumonitis both have experimental evidence in their favor, but whether one or the other causes damage to lung tissue the infecting organism reaches it either by aspiration or as in non-operative cases by the descending route as explained in Blake and Cecil's (14) studies on pathogenesis of pneumonia.

The factors which the champions of one or the other of the above three theories fail to emphasize sufficiently are first, the increased virulence of the exciting organisms at certain times of the year and in different years. Secondly, the lowered resistance of the individual as a result of concurrent upper respiratory tract infection. Third, the factors of exposure before, during and after operation, to cold and dampness and fourth, the relaxed vaso motor tone in the shocked patient. Given any one of these factors plus any one of the first three pathological processes and the patient will more certainly develop a pneumonitis. Eliminate the latter factors and a patient with a small pulmonary infection or a partial atelectasis or aspiration of contaminated throat secretions stands an excellent chance of recovery without an actual pneumonitis—an actual inflammation of lung tissue.

Our statistics at the Presbyterian Clinic are of interest in this respect. In 1915-1916, we reported an incidence of 23 per cent, of pneumonitis in 3,719 operated cases. In 1924 our incidence was 2 per cent. In 1925 it had decreased 14 per cent. This reduction, we feel, is due to the fact that we have advised against abdominal operations of choice during the late winter and early spring season when respiratory infections are most prevalent. This, we feel is especially important in the upper abdominal cases.

That an upper respiratory infection, recent or concurrent, is a real factor is demonstrated by the fact that although in 1924 our incidence was 2 per cent and in 1925 14 per cent, the incidence of pneumonitis in patients giving the history of a very recent or concurrent cold was 15 per cent in both years. The great majority of these patients came to the hospital with such acute lesions as peritonitis or acute ileus where operation was not a matter of choice. These

figures showing an incidence ten times greater than the general incidence prove beyond question that the elimination of the factor of upper respiratory infection before and after operation is the bounden duty of the operating surgeon, and a duty not to be delegated to the interne or the nurse.

I should like to emphasize, as I did in my paper in 1918 (9), the importance of eliminating the carelessness that exists, even in our best teaching hospitals, with regard to the exposure of patients to the factors that so strongly predispose to upper respiratory infections during their stay in the wards. This applies as much to the poorly compensated cardiac or the nephritic case on the medical ward as it does to the surgical patient.

These factors are the exposure of the patients to draughts, to which they are entirely unaccustomed, to chilling during examinations, ante-operative preparations and post-operative treatments. Carefully and conscientiously look into the routine—what a dreadful word that is in a hospital—handling of your ward patients and take note of the many chances that a patient takes in the course of his first two or three days before and after operation and then begin the difficult task of cutting hospital red tape and overcoming the inertia of your ward tradition. The conscientious surgeon will be repaid in the reduction of his post-operative pulmonary complications.

TREATMENT OF ARSENICAL ECZEMA

By BINFORD THRONE, M.D., LAIRD S. VAN DYCK, M.D., ELEANOR MARPLES, A.B., AND C. N. MYERS, PH.D.

From the New York Skin and Cancer Hospital, New York City

IN a recent paper, the authors reported a series of patients suffering with eczema in whom Arsenic was found to be the causative agent of their skin trouble. The chronic arsenical intoxication responsible for their skin disease was not, as a rule, acquired through medication, but in practically all cases through industrial contact.

As we stated in the former paper, this is the first time that scientific proof has been offered showing that this metal is the actual cause of the disease in a very large percentage of patients applying for treatment for eczema. Many authors, among them Ehrmann* deny that arsenic given in the form of medication or for the purpose of poisoning can cause eczema; they say that its external contact can cause an eczematoid dermatitis but not a true eczema. It is our contention that this external contact actually results in the absorption of the chemical and that it is its action on the body tissues and blood in these

cases, which results in those definite skin changes which are called eczema.

This chronic intoxication can be acquired through the respiratory tract through contact with Arsin (AsH_3), sublimed arsenic, powders or solutions containing arsenical compounds such as arsenious acid, lead, copper or calcium arsenite, etc. Workers exposed to the above chemicals may also have some absorption through the alimentary canal and through the skin.

The occupational histories of our patients show the following industries represented where the poisoning was acquired in the above manner. First, through the respiratory tract—submarine work, radio and automobile battery charging establishments, electroplating works, chemical factories for the manufacture of sulphuric and other acids, smelters and refineries for the reduction of metals from their ores or for the refining of metals, insecticide factories and general chemical

factories, printing establishments where gilt or bronze powder is used, farmers and gardeners. Second, the alimentary canal seems to be the chief portal of entry where woollen goods, which are sprayed with a solution of an arsenical compound as a moth preventive, is used. This group of workers is represented by tailors who put the cloth in their mouths, glucose and candy factory workers, workers in sizing and dextrin, printers and bookbinders, fruit handlers, furriers who handle raw furs. In this group, as in the first, there is also some absorption through the skin. Third, in machinists and metal workers who handle brass, copper and zinc, the absorption is chiefly through the skin.

Types of eruption which would cause suspicion of a probable arsenic causation. The most common clinical type seen is the papulo-vesicular variety with a very extensive distribution on the face, neck, limbs especially the flexor surfaces, and the trunk. Associated with the eruption there is a marked oedema of the affected parts and a profuse serous discharge. Frequently on the elbows there is found some psoriasiform scaling. On the back of the neck and upper part of the back one often sees a tendency for the skin to appear as though a papillomatous growth was developing. The lips are frequently involved and are crusted or scaling and oedematous. The palms are involved in most cases and may show either a moist oozing condition or more frequently typical arsenical keratoses which, as is known, affect the outer part of this region rather than the central triangle. These lesions are also frequently found on the inner sides of the fingers at the junction of this part with the palmar surface, but sufficiently removed from the palmar surface to show that they are not the result of chronic pressure (occupational callosities). The tips of the fingers are often dry, brittle, hyperkeratotic and fissured. There is often a corresponding nail involvement and a thickening of the nail bed. There is also in these cases increased pigmentation which of course is most marked in those of long standing.

In other cases with extensive involvement, the papulo-vesicular features are not marked and the rash resembles an universal exfoliative dermatitis. In this type of case there is extreme oedema of the skin—a tendency for erosion of the horny layer, profuse serous discharge and infiltration and thickening of the whole skin. This infiltration and thickening is in contrast with the skin as seen in the dermatitis from the arsphenamines. The distribution of the rash in this type is extensive and in most cases it is practically universal. Cases of both these types (which might be designated as the papulo-vesicular and the erythematous types) are seen in which the eruption is less widely distributed. These may show a rash of either of the above types limited to one area

or disseminated areas may be seen on the face, trunk or limbs. The development of the skin condition in places which do not come in contact directly with the arsenic containing substance would point to a systemic cause rather than to a local irritant as the etiological factor in the production of the eczema.

Associated with the skin symptoms at times are others which seem to be due to the action of the arsenic on other organs. One case gave a history of a chronic gastritis. This condition cleared up entirely as his skin disease improved without any special gastric medication. Another case showed a beginning sub-capsular cataract. It is our opinion that study of this type of chronic poisoning will show that many obscure internal conditions are due to this factor.

Diagnosis. Clinical diagnosis is only possible when a definite history of exposure is obtainable. This exposure may be quite remote from the date of the development of the skin symptoms. It is, therefore, necessary in obtaining histories of these cases to inquire very carefully as to the patient's occupational history for several years—at least three—previous to the appearance of the rash. The findings of the lesions on the hands and fingers as described above are always of great importance. The papillomatous condition at the back of the neck seems to be diagnostic.

The laboratory diagnosis was described in a previous paper. In brief, this consists of a blood and urine examination for arsenic before any treatment is instituted. The urine usually shows none, and the blood may show a trace or an amount too small to be pathologic. An intravenous injection of a freshly prepared solution of 0.5 gram of sodium thiosulphate in freshly distilled and sterilized water is given, after which the urine is collected for 24 hours and measured and examined for arsenic. In cases of eczema due to arsenic it was found in amounts of 0.87-1.062 per 100 grams of dried specimen.

After the establishment of the diagnosis, the intravenous injections of sodium thiosulphate are continued. 0.5 gram is given in freshly distilled sterilized water. The solution is prepared at the time of the injection. This point cannot be emphasized too emphatically. Solutions on standing deteriorate, a deposit or precipitate of sulphur is seen in old solutions and they are not as active as are those freshly prepared. The injections are given every third day. On the alternate days one gram of thiosulphate is given by mouth before breakfast in one dose dissolved in about four ounces of water. These injections are continued as long as clinical improvement is seen. As was stated in our paper on "Arsenic as an Etiological Factor in the Genesis of Eczema" there are tides of arsenic excretion in which there is an "Ebb and Flow

of Arsenic" With a diminution or cessation in the elimination of the chemical there develops either a recurrence or exacerbation of the clinical symptoms. With this retention of the arsenic there is seen a condition suggesting a vagotonia. It would seem that the sodium had over-stimulated the vagus and in some way this inhibits the action of the thiosulphate. When this condition develops the injections of thiosulphate should be discontinued for a few times and a substance which stimulates the sympathetic portion of the vegetative nervous system given. Calcium has this power and in these conditions we give calcium chloride. The preparation which we use is known as "Afenil." We give this in 5 c.c. doses three times a week for one week, after which the injections of the thiosulphate are resumed. The calcium seems to overcome the vagotonia, stimulates the sympathetic and thus activates the thiosulphate and the excretion of the arsenic is re-established. Clinical improvement is again noted. As was stated in the article on arsenic and eczema, blood chemistry in these cases shows a comparatively high blood sugar and a perverted chloride metabolism. On account of the improper carbohydrate metabolism, it is advisable to restrict carbohydrates in these cases. It has been our practice to eliminate all cereals, potatoes and macaroni, and allow only two or three small slices of whole wheat or rye bread a day, sugar is absolutely eliminated from the diet. Fresh fruit such as agrees with the patient and where sugar content is low is allowed. Fresh green vegetables of all kinds are allowed. It has seemed best to eliminate the heavy meats (purin containing), a moderate amount of chicken and lamb is allowed, and we have seen no bad results from them. A study of the blood uric acid is being done and will be announced later. Milk and mild cheese are allowed. Chlorides are eliminated as far as possible. External treatment is limited to soothing, protective remedies

which do not contain arsenic. We have had one case with an arsenical rash which was acquired through the use of a calamine and zinc lotion. Chemical examination of the lotion showed a high arsenic content. This point we think is of great importance. Arsenic can be easily absorbed through the eroded edematous skin, and the use of a preparation containing it would only be "adding fuel to the fire." We have found the following useful:

R Amyli Oryz		R Aquae Calcis	100.
Talc Venetian	aa 10	Oler Olivarium	150
Aquae Calcis	15	Tragacanth	q.s.
Oler Olivarium	120	M Sig External Use	
M Sig Ext use			

To either of the above Phenol 1—2 per cent and Menthol $\frac{1}{4}$ per cent may be added, or a dusting powder such as the following can be applied especially when the serous discharge has stopped:

R Camphor trit	6
Zinc stearate	16
Powdered starch	50
M Sig External use.	

For the oozing edematous condition of the face and lips, wet compresses of boric acid 1 or 2 per cent in camphor water are very beneficial.

In conclusion, we would say that in cases of eczema where arsenic is the causative agent, this line of treatment is specific.

The duration of the treatment depends, as in other conditions, on the duration of the disease when treatment is first instituted. In old cases the arsenic is firmly "fixed" in the body tissues and its elimination is necessarily slow.

RAYNAUD'S DISEASE—A PATHOLOGIC ENTITY—REPORT OF A CASE FOLLOWING LERICHE OPERATION

By W. F. CUNNINGHAM, M.D., NEW YORK CITY

RAYNAUD'S disease is generally regarded as a functional vascular disturbance, dependent on defective vasomotor control. The object of this paper is to record the pathologic changes in a typical case, to proffer the view that the disease is a pathologic entity, and to relate the course following removal of adventitia from the brachial and femoral arteries.

In 1862, Raynaud (1) published his mono-

graph on this disease, reporting twenty-five cases, five being personal observations. From this time dates the syndrome by his name—the symmetrical tendency—local syncope—local asphyxia and gangrene apparently without any organic vascular lesions. Two cases with autopsy were reported but the pathologic histology was inadequate for conclusions. In one of these cases there was hypoplasia of the aorta, femorals, brachials, anterior and posterior tibials and mitral valvulitis.

* From the Department of Surgery, College of Physicians and Surgeons, Columbia University, New York City and Bellevue Hospital, First Surgical Division.

In 1899, Monro (2) collected from the literature 145 cases and concluded that there was no anatomical condition, either gross or minute, peculiar to the disease, although reference is made in some of the cases to occlusion of the arteries

Fig 1—Digital branches—topography—cross section through base of middle finger

by thrombi and calcification. The pathological reports are meagre and undoubtedly other well recognized conditions are included in the group

The literature on Raynaud's disease is abundant but most of it consists of case reports describing the disease associated with many infectious diseases

In 1907, Fox (3) in an article—"Notes on Some Cases of Symmetrical Gangrene—Relation to Arteritis"—reported three cases without pathologic reports

Lisser (4) in 1910 reported a case associated with syphilis and gives an extensive bibliography of the association of the disease

In 1910, Buerger (5) stated that—"We possess no data which tend to show that erythromelalgia or Raynaud's disease is dependent upon organic obliteration of arteries or veins"

It is not the purpose of this paper to discuss aetiology but to record the findings

CASE REPORT

J A Age 33 Nativity—Poland Admitted to the First Surgical Division of Bellevue Hospital on December 13, 1924 Five years ago the right big toe became red and swollen There was constant severe pain Several minor operations were performed—the toe finally sloughing off at the metatarsal joint At the same time he lost the terminal phalanx of the second left toe

Several weeks prior to admission he began to have trouble with the right middle finger—pain and swelling followed by gangrene of the tip This was attended with bluish discoloration of the hands at times and a little later the left middle finger became involved For years the patient had been so susceptible to cold that at times he

would wrap his feet in cotton. Venereal denied. Wassermann, negative.

The physical examination was negative except for evidence of mitral valvulitis and the condition of the extremities The radial pulses at times were absent, at times equal and of good volume The dorsalis pedis pulses were present at times and absent at others During the absence of pulsation the pain was markedly aggravated. There were periods of blanching and cyanotic blush.

The right big toe and the tip of the left second toe were absent The right middle finger presented a loss of substance ventrally to the middle of the second phalanx with undermining of the nail and a cyanotic blush of the remainder of the finger There was gangrene of the tip of the left middle finger

For three days both radial pulses had been absent A Leriche operation was performed on the right brachial artery just above the elbow, removing almost 6 cm of adventitia At the same time the right femoral artery was operated on

Fig 2—H & E Stain—A. Patent Vein—B Artery—1 Heaped up endothelial cells 2. Thickened intima 3 New formed blood vessels 4 Internal elastica 5 Fibrosis in muscularis 6 Fibrin and blood corpuscles

and 7 cm of adventitia removed en masse—2 cm from the common, 2 cm from the deep and 5 cm

from the superficial. Both of these vessels immediately contracted to about one-half their original calibre and were without pulsation at these sites. The left extremities were not operated on. The night following operation was attended by less pain than he had had for several days. The pulse returned to the right radial that afternoon.

The accompanying chart shows observations made on the various pulses

Fig 3—Weigert-Van Gieson stain showing prominent internal elastica. Same as Fig 2

	Radials		Dorsalis Pedis	Post Tib Rt. & Lt.	Popliteal	
	Rt.	Lt.	Rt. & Lt.		Rt.	Lt.
12/20/24	+	—	—	—	+	+
12/21/24						
10 00 A. M	+	—	—	—	+	+
12 30 A. M	+	—	—	—	+	+
8 00 P. M	+	—	—	—	+	+

From December 20 to December 28 observations were recorded on the pulses as in Chart 1. The right radial and both popliteal pulses were present. The left radial, both dorsalis pedis and both posterior tibials remained without pulsation.

The pain became so severe in the right middle finger that on January 5, 1925 it was amputated under local anaesthesia. Practically no bleeding was encountered. The wound healed promptly.

Pathology Macroscopic Examination Specimen consists of a finger amputated at the metacarpo-phalangeal joint. The tip of it presents loss of substance with ulceration. The nail is undermined. The epithelium proximal to this is desquamating en masse.

Microscopic Examination H & E stain. Section of digital arteries (Figs 1, 2, 3). The adventitia is normal. The media shows a patchy fibrosis. The intima is greatly thickened, eccentric in type and presents a hyaline degeneration, two well-formed patent vessels are present. The intimal lining is heaped up, the cells being columnar instead of flat. The lumen is greatly reduced and contains a few red blood cells. Another digital branch shows a similar but more pronounced reaction, here the intimal lining is composed of several layers of cells and the lumen is almost obliterated. Van Gieson stain shows to better advantage the fibrosis both in the intima and the media. The Weigert stain brings out nothing except a markedly hypertrophied internal elastic lamella.

Diagnosis Obliterating Endarteritis. Hypertrophy of Internal Elastica.

The writer has observed the various phenomena of Raynaud's disease in patients with advanced arterio-sclerosis and in the more acute lesions following exposure to cold, such as trench feet, and since writing this paper, has reviewed slides of another case said to be a typical case of Raynaud's disease. The arterial changes are those of obliterating endarteritis.

Summary

- 1—The patient showed all the clinical phenomena of Raynaud's disease.
- 2—The disease is attended by definite vascular changes, arteritis with obliterating endarteritis.
- 3—There was definite improvement symptomatically, and a constant presence of the radial pulse following the Leriche operation.
- 4—Raynaud's disease is a symptom complex associated with genuine arterial lesions.

THE MECHANISM OF NONSPECIFIC THERAPY

By MAURICE J LEW, MD, NEW YORK CITY

NONSPECIFIC therapy has been employed much longer than the designation is known. It has been heretofore generally described as a method of treatment in which foreign agents are used to improve general body conditions. This uncertain and quasi-empiric explanation may account for its erstwhile lack of favor to the practitioner and for its negligible importance in medicine.

Nonspecific therapy does not necessarily depend upon the agents used. Nonspecific therapy is based upon the observation that the body's inherent resistance powers—the physiologic reactions of the tissues and the entire organic systems toward infections—are increased when foreign proteins are injected into the economy.

Those who employ this therapeutic method should be primarily familiar with all the hitherto known facts about the body's resistance powers so as to judge how, when and where a stimulation of the same may prove helpful in medical treatment.

Our knowledge of the organic basis of the body's inherent resistance powers is still far from complete, but enough is known to establish the existence of such powers. It is not the purpose of this paper to give a review of the methods by which scientists in the last ten years have studied this vast field, only the results that are useful and important to explain the mechanism of nonspecific therapy are pertinent.

An understanding of how nonspecific agents act will alone enable the practitioner to find a clear indication of the type of cases in which nonspecific therapy should be used and how, in individual cases, the course of nonspecific treatment should be arranged.

Nonspecific treatment as a stimulation of body's resistance has been used for centuries. Every stimulation of the skin by irritating plasters—so-called fixation abscesses, heat, cold, burns, poultices, etc., has been nothing more nor less than frequently a very harsh and not always safe method of helping the patient's condition by increasing his own power to overcome disease.

Since the work done by Petersen, E F Mueller, Weichardt (1) and many others we know that two great organic systems participate in the body's resistance.

If an infection enters any part of the body a reaction, known as inflammation, takes place. There are many theories about the nature of inflammation. Our interpretation of the actual findings is as follows. Following infection, a reaction of the surrounding tissues occurs, the vessels become dilated, they are filled with leucocytes and the cells of the tissues involved increase their metabolism. Microscopically the cells appear swollen, their protoplasm becomes cloudy, small

round cells gather and the native tissue cells, theretofore immobile, begin to move and to show phagocytic properties. Following the studies initiated by Cohnheim (1868) and followed since by many investigators, there first occurs a dilation of the vessels, this is to be considered as an active action of the vasodilating nerves, always in evidence as long as these nerves are effective and there is actually no disease which eliminates or decreases their action.

A second reaction is an increase of the number of leucocytes in these vessels. Leucocytes are not produced in the tissues involved. The bone marrow system alone creates them and if their numbers increase in any particular part of the body, their source is elsewhere.

A third reaction is of the tissues involved. For therapeutic purposes, it is impossible to augment a restricted and limited tissue reaction excepting through the production of added numbers of leucocytes, these may reach exceedingly and unlimited high figures. Therefore, the leucocytes constitute the only medium to increase the body's resistance in a local inflammation.

If one injects a tissue irritating agent into a healthy body, an immediate increase in the action of the bone marrow system follows. This is manifested by a new production of leucocytes which, after from 8 to 10 hours, appear in every vessel of the body and then participate in the formation of an abscess at the place of injection. Many physicians therefore believe that an agent which produces leucocytes in increased numbers or which stimulates even the healthy body to produce these leucocytes, is a great help therapeutically. This idea is entirely erroneous. An agent, the administration of which is promptly followed by a new production of leucocytes, shows that it is itself toxic and that the body has to exercise great effort to eliminate it. The leucocytes appearing in the blood stream after the injection of such a toxic substance are a manifestation of the attempt of the body to eliminate this foreign agent. There is no doubt that in case of a local inflammation one part of the thus newly produced leucocytes appears at the site of infection increasing the discharge, thus being of help in the ultimate eradication of the disease, but if the body has to eliminate such a toxic agent, all of its efforts to this end are lost as far as the original disease is concerned. In other words, there is a loss of much-needed energy—a diversion of the body's resistance powers to rid the system of a new hostile agency, whereas the object sought was to eliminate the toxin of the disease.

Therefore, it has been necessary to develop an agent which is able to act as a stimulator of the

bone marrow system, without being toxic enough to induce a reaction as described above. From this idea, developed in 1918 by E. F. Mueller, (2) studies were begun to produce an agent which would prove useful for therapy without introducing additional toxic substances into the human economy. These studies following the idea of Schmidt (3) who first introduced milk into this therapy, were successful and a nontoxic albumen preparation was developed which has the following properties. If injected into a healthy body, no clinic manifestations occur. Even doses of 20 or more cc of this milk-albumen suspension (Aolan) which contains the same per cent of albumen, as milk, do not produce any of the known reactions of other nonspecific agents such as fever, chills, leucocytosis and smarting. However, its administration in healthy bodies is not without reaction, even if clinically no symptoms occur and the patient is not conscious of the same. Since the development of this germ- and toxin-free lactalbumen solution, other milk derivatives for which like claims are made, have been produced.

The first symptom after the injection of such an agent in the healthy body consists of a sudden reaction of the entire leucocytes in the body. Careful examinations will show that the leucocytes drop slowly in the periphery and research work has demonstrated that they gather in the splanchnic region. (4) This is only one effect of a great systemic action involving the entire involuntary nervous system. The involuntary nervous system controlling the vessels, immediately stimulates the entire bone marrow system and the entire vasocontrolling nerves. But after the use of such a nontoxic agent, the clinical evidence of this reaction is so minor that the normal tissues equalize it immediately and there ensue no clinical symptoms.

This is very much different in patients with general or local infections. The same stimulus of the involuntary system becomes immediately noticeable and while the same changes in the leucocytes occur, the tissues involved do not equalize this reaction. However, the bone marrow system in every case of infection is in a state of slight reaction which responds immediately to any trifling stimulus, thus increasing the process of resistance. This can be demonstrated clinically as well as serologically. If, for instance, an abscess as a sequel of a staphylococcus infection exists near the kidney, the bone marrow system produces leucocytes in greater number than usual. These leucocytes contain properties to phagocyte staphylococci in higher measure than other germs. We furthermore know that there are bodies produced which are able to attack staphylococci by agglutination and other serologic manifestations and that the nonspecific stimulus reaching the bone marrow system immediately increases this process, already begun.

Again, if, in the first days of a typhoid fever infection a protein agent is given early, the typhoid agglutination is increased. If in a normal human being who has had an injection of typhoid germs for vaccination purposes a protein injection is given, the already increased agglutination power of the serum will be increased but if the same protein is given to a healthy human being without previous injections of typhoid vaccine, the very slight agglutinating power against typhoid germs (perhaps 1:50) is in no manner changed. There is no longer any production of leucocytes as in the case of a staphylococcus abscess near the kidney or wherever it may be. In other words, we are not able with nonspecific agents and with the nonspecific stimulus following their use which reaches the bone marrow system, to produce any reaction other than to increase an already started reaction of resistance of this particular organ. We know that the stimulus is purely nonspecific. The reaction on the other hand is absolutely specific and follows the line of the previously started reaction against this type of germs already present in the body.

This demonstrates that the use of nonspecific agents has to be limited to the treatment of infectious cases only. It is impossible to prevent infection by nonspecific agents, but after an infection has occurred, nonspecific agents will be of the greatest value for treatment purposes. If nontoxic agents are thus employed it becomes possible markedly to increase the body's resistance. This treatment will be especially useful when all other means to improve the local or the general condition fail. Local infections such as furunculosis, gonorrheal infections of the urethra as well as of the epididymis and joints and other local infections are examples. General infectious diseases such as puerperal septicemia in their early stages and similar acute or subacute conditions are also a proper field for nonspecific therapy.

If germ- and toxin-free protein agents are injected into the human economy the question arises: how does the bone marrow system react? There is no chemical or physical contact between the injected agents and the bone marrow system. The effect is produced not by the absorption of the agent and its subsequent distribution throughout the body, thus to reach the bone marrow in a very diluted condition, but the contact is made by an immediate reaction of the involuntary nervous system, if the protein from the circulation enters the tissues and so comes in contact with the tissue cells. This reaction primarily leads to a dilation of the vessels of the bone marrow system and then to a new formation of myeloid tissues from which leucocytes are produced and distributed.

The second question which arises is of great interest physiologically as well as therapeutically.

How is it possible that newly formed leucocytes reach the site of the infection? It was discovered that leucocytes gather immediately wherever vessels are dilated by an active nervous stimulation. We know that in infected tissues the vessels are dilated and we furthermore know that the stimulus of the involuntary nervous system created by the administration of a nonspecific agent is not equalized as in a healthy body and particularly not in the area of infection. In all these areas in the infected patient it is clinically known that the vessels are no longer in their usual condition as to calibre. Thus the same stimulus which reaches the bone marrow system reaches these dilated vessels. There the already existing dilation will increase, by this vasodilating stimulus and in these dilated vessels leucocytes and antibodies are retained, thus producing a focal reaction (4).

SUMMARY

A nonspecific agent injected into the body for therapeutic purposes, should not contain toxic substances. Toxic substances have to be eliminated. For this elimination an effort of the body's resistance is required and a loss of cells and of antibodies occurs. An extra burden is placed upon the system's resources.

In using nontoxic agents for the administration of nonspecific therapy, no clinical manifestations of a reaction (fever, chills, nausea and so forth) occur, either in healthy individuals or in diseased patients. The clinically unrecognizable reaction is the same in both. Two organic systems become influenced—the involuntary nervous system and the bone marrow system. The involuntary nervous system carries the stimulus to the organs and to the tissues of the entire body. But only such places react in which the tissues are inflamed, which stage is characterized by dilation of the vessels. This stimulus causes an increase of this latter reaction. This leads clinically to a focal reaction at the site of the infection and furthermore brings about an increase of all symptoms thus demonstrating the incidence of a fortified resistance—i. e., formation of leucocytes,

formation of antibodies, increase of focal reaction, followed by overpowering of the hostile germs, rehabilitation of the theretofore infected tissues and subsequent clinic improvement.

It has not been the aim of this paper to stress only the clinical experiences by giving the explanation of how nonspecific therapy acts by way of a cooperative reaction of the bone marrow and the involuntary nervous system. It is desired to show that in every infection this cooperative reaction, whereby the physiologic functions of resistance are strengthened, takes place. If this reaction can be increased by therapeutic measures, the latter become useful in the treatment of local and general infections.

The course of recovery from every infection takes place in the presence of certain definite known clinical symptoms. Trichophytia is not accompanied by fever but the same sycosis produced by staphylococci is often coupled with a feverish reaction. Therefore, it may be understood in an individual case that the patient with a fever-producing germ will react with fever after nonspecific and nontoxic agents are injected, not because the agent has produced the fever but because the elimination and the absorption of this germ by the body's own functions, increased by nonspecific therapy, gives rise to a feverish reaction.

If all these points are known to the practitioner he will be able to use nonspecific therapy helpfully, especially in infected conditions, wherever they occur, if he limits the indications to infections only and if he considers that in every individual case nonspecific therapy acts only by increasing the inherent body resistance.

REPORT OF A CASE OF CORONARY EMBOLISM WITH RUPTURE OF THE HEART

By WALTER F. BOPP, M.D., NEW YORK CITY

RUPTURE of the heart is sufficiently uncommon to warrant the report of such a case with the autopsy findings observed at the Lutheran Hospital of Manhattan. The history briefly is as follows:

Male, Russian, aged 46 years.

Family history is negative.

Previous History—Usual diseases of child-

hood, since then perfectly well except for an attack of acute gonorrhea five years ago. Married twenty-seven years, wife and three children living and well, no miscarriages.

Present Illness—Five weeks ago, while traveling in Virginia, was taken acutely ill with severe pain in the right shoulder, moderate pain in the right upper quadrant of the abdomen with much

nausea but no vomiting, there was high fever accompanied by profuse sweating. After five days the pains disappeared and have not annoyed him since, the sweating persisted for another two weeks, especially during the night, then gradually ceased. As no physician was available he returned to the city. Since then he has not felt well without, however, having any definite complaints, has lost ten pounds in weight in the past five weeks, appetite has been very poor, bowels obstinately constipated and move only with laxatives, there is occasional cough without any expectoration.

On November 27 he was admitted to the Luthern Hospital with a temperature of 102.4, during the six days that he was in the hospital this continued irregularly between 99 and 102, the pulse varied between 90 and 120, regular but of poor quality.

Physical examination on admission showed a well-nourished well-developed adult male, acutely ill with skin and mucous membranes pale.

Eyes, ears, nose, mouth and throat normal, tongue moist and badly coated, teeth in poor condition.

Lungs—A Few fine rales over both lungs posteriorly, otherwise clear.

Heart—Left border 1 centimeter to the left of the nipple line, right border 5 centimeters to the right of the Sternum, apex impulse in the 5th intercostal space—very weak, heart sounds faint and of poor quality, there are no murmurs to be heard.

Abdomen—Flat, not tender, no masses felt, spleen not palpable, liver slightly enlarged—about one finger below the free ribs, slight tenderness over the gall-bladder region.

Extremities are normal.

On December 2, four days after admission, there is marked crepitation over the gall-bladder region with considerable tenderness. In view of these findings, combined with the history and temperature curve a tentative diagnosis of cholecystitis with cholelithiasis and chronic myocarditis was made.

Laboratory examinations gave the following results: blood count—2,800,000 red cells with 62 per cent hemoglobin, white cells 11,000, polymorphonuclears 67 per cent, lymphocytes 24 per cent, mononuclears 9 per cent. Blood culture sterile, Wassermann and Widal reaction negative. Chemical blood examination showed: Urea 13.6 mg, uric acid 4.7 mg, creatinin 2.9 mg, blood-sugar 0.16 per cent.

Urinalysis—Amber, acid, cloudy, specific gravity 1028, faint trace of albumin, no sugar, acetone or diacetic acid, microscopic examination showed many hyaline and granular casts.

Report of the X-ray examination by Dr. William T. Stewart was as follows: Liver shadow considerably enlarged, just beneath the free bor-

der we see shadows suggestive of gall stones. Complete gall-bladder examination advised.

These reports seemed to confirm our original diagnosis and surgical interference was being considered.

Two days later, while at supper, the patient suddenly lost consciousness, and developed all signs of an acute shock, the face and lips became pallid, the body covered with a profuse cold, clammy sweat, breathing very slow and shallow, the pulse imperceptible. A hyperdramatic of 1 cc adrenalin was given at once with prompt reaction, the pulse again became perceptible but very weak and of poor quality, consciousness returned, the patient complained of marked weakness but had no pain, the temperature rose to 103.

At ten A.M. the next morning a physical examination showed skin and mucous membranes slightly icteric, the gall-bladder enlarged and easily palpable but not tender, liver enlarged to two fingers' breadth below the free ribs, abdomen soft, no evidence of any peritoneal irritation. The heart action is very poor, the heart sounds are distant and muffled—the muscular tone is of poor quality and weak, marked dilatation to the right, no murmurs audible, temperature 99. Impression—infectious thrombus of one of the coronary arteries.

While dictating these findings to the interne the patient, much interested, was sitting up in bed. Without warning he suddenly fell back unconscious, with generalized convulsions, the pupils dilated widely and did not react to light, the mouth was drawn to the right, after two minutes the convulsions ceased, the pupils contracted to pin points, respirations two per minute and quite shallow, no pulse or heart action. Intracardiac injection of adrenalin restored a feeble heart-action which, after two minutes, stopped and could not be restored. Diagnosis—Coronary embolism with a thrombus in the heart and a probable cerebral embolism.

Autopsy performed by Dr. Frank Grauer with the following report: Permission to open the head was refused, skin icteric. Thoracic cavity—left lung shows emphysema and anthracosis, peribronchial glands swollen and greatly pigmented—there is no oedema, bronchial tubes show evidence of a bronchitis—pulmonary vessels are normal. There are adhesions between the lung and the parietal pleura. Right lung shows considerable enlargement of the peribronchial glands, anthracosis, bronchitis and a slight oedema, there are no adhesions.

Heart—The pericardial sac is greatly distended and covered with fat—it measures at its base $7\frac{1}{2}$ inches and its length is $6\frac{1}{2}$ inches. The heart appears to be pushed down into its lower right corner, on opening the pericardial sac we find it filled with a bloody fluid and a large clot, the size of two fists. There are ad-

hesions of the left ventricle to the visceral layer of the pericardium

On opening the left ventricle we find a coagulated degenerated mass in the left anterior wall of the ventricle and the whole ventricle filled with an ante-mortem clot. No attempt is made to find the exact point of perforation, as the whole left wall was entirely destroyed. The mitral valve admits only $1\frac{1}{2}$ fingers, showing a stenosis. The aortic valves are normal. There is an arterio-sclerosis of the Aorta with fatty patches. The left coronary artery shows an arterio-sclerosis and is obstructed $\frac{3}{4}$ of an inch from the opening where a calcareous deposit can be felt. The right ventricle on being opened shows normal muscle fibers, the pulmonary and tricuspid valves are normal.

Abdomen—There is no free fluid in the peritoneal cavity, the spleen is enlarged, rather hard and shows evidence of a passive congestion.

The left kidney is firmly fixed, bound with a large amount of fat and greatly enlarged, the capsule is slightly thickened but strips off easily. The kidney appears to be normal as far as the cortical and pyramidal substance is concerned. There is a small nodule, the size of a pea, in the cortex—the remnant of an old infarct. The right kidney is found misplaced—at first it appeared to be absent but it was found firmly attached deep in the pelvis. It is very small, the

pelvis is small and there are few calices. It is difficult to find the right ureter, it runs upward, then bending at an acute angle, downward into the bladder. The renal vessels are firmly fixed in the connective tissue of this region showing that it is a misplaced kidney. The orifices of both ureters are very small.

The liver is slightly enlarged and congested, the portal veins stand out distinctly and, on being cut, are full of blood. There is an old scar on the lower part of the right lobe—evidence of a former peri-hepatitis. The gall-bladder is moderately distended—on opening the duodenum and compressing the gall-bladder there is a discharge of muco-purulent fluid into the duodenum. The mucous membrane of the gall-bladder is congested and inflamed, no stones are found.

Pathological Diagnosis — Arterio-sclerosis, haemo-pericardium, embolism of the left coronary artery, with arterio-sclerosis and a calcified obstruction, rupture of the left ventricle, pericardial adhesions, emphysema, anthracosis, adhesions of the left lung, misplaced right kidney, acute cholecystitis.

We have then a case of coronary embolism with rupture of the left ventricle, simulating an attack of cholelithiasis. In conclusion I wish to express my thanks to Dr. Franklin Welker, medical director of the Lutheran Hospital, for permission to report this case.

A REVIEW OF SOME OF THE ACTIVITIES OF THE STATE INSTITUTE FOR THE STUDY OF MALIGNANT DISEASE, BUFFALO, NEW YORK*

By BURTON T. SIMPSON, M.D., Director

INTRODUCTION

IT might be of interest to some of you to learn something of the origin and development of the State Institute for the Study of Malignant Disease at Buffalo, and I will, therefore, take this opportunity to tell you a few facts concerning it. The Institute was the conception of Dr. Roswell Park, professor of surgery at the University of Buffalo. His idea was to study malignant disease from the laboratory standpoint. I think this idea of Dr. Park's originated during his stay at the Pasteur Institute, where he spent a year, preparing himself to give the Mutter Lectures on surgical pathology.

In 1898, the State Legislature at the request of Dr. Park and others, appropriated \$10,000 for the laboratory study of cancer and the Medical College of the University of Buffalo furnished quarters for the purpose of this research. Dr. Harvey R. Gaylord was put in charge of the laboratory and he, with one as-

sistant and a stenographer, comprised the staff of the laboratory at that time.

It might be mentioned that this was the first laboratory for the exclusive study of cancer to be established in the world.

From this modest start the Institute has gradually grown until at present it comprises the Gratwick Laboratory, in which are housed the pathological, bio-chemical and physical laboratories, the hospital, with its 25 beds, for therapeutic research on human beings and the biological station at Springville, where much of the animal experimentation is carried on.

The Institute employs about 70 individuals, the majority of whom are engaged in research activities.

Although much routine work of various sorts is carried on, and many patients are treated who are not of definite research value, still the original purpose of the laboratory, viz, the research investigation into the cause and cure of cancer, is maintained.

The staff is composed of a director, a pathologist, a biologist, a biological-chemist, a physi-

* Read before the Association of Public Health Laboratories November 12, 1926 Albany, N. Y.

cist and internist and a surgeon. The director has general charge of the activities of the Institute and it is his duty to correlate the activities of the several departments and to stimulate research along various lines.

The Institute is made up of the following departments: pathological, bio-chemical, physical, biological and therapeutic. Each department has its chief with one or more assistants. The chief is responsible to the director for the conduct of the work in his department.

ACTIVITIES

The activities may be roughly divided into routine and research. The routine work consists of, (1) A state-wide free diagnostic service of tissue pathology. This amounts to the examination of between eight and ten thousand specimens yearly. (2) The routine examination and treatment of patients afflicted with malignant disease. This totals over five thousand hospital and dispensary calls yearly. Besides these main activities there is the routine clinical analysis made for the hospital and dispensary patients, the pumping and measuring of the radium emanation and other similar activities.

RESEARCH

I feel that you are more interested in our research activities and I will therefore, spend the time allotted to me to touch upon some of the more important ones. As you know, there are two outstanding problems in cancer research. The one is to determine the cause of this malady and the other is to find its cure. Therefore, all research activities are either directly or indirectly centered about these two problems.

I will first consider some of our research activities in regard to etiology. In the early days of cancer research great efforts were put forth to cultivate a specific organism from cancerous lesions, for at that time organisms were being found to be the specific cause of certain infectious diseases and it was thought by some investigators that cancer might be an infectious disease. The best bacteriologists in the world spent much time and energy in these attempts. Occasionally some investigator found what he thought was a specific organism, but subsequent investigation did not substantiate these claims. The net result of all this extensive research showed, that either malignant neoplasms were sterile, or an organism could be cultivated from them, which could be placed among the known bacteria.

In the early period at our Institute, we spent several years trying to find a specific organism as the causative agent in cancer. From the results of this work and also from the work of others, we concluded that bacteria had

no specific relation to the origin of cancer.

In 1902, Jensen, of Copenhagen, succeeded in transplanting a primary tumor, found in a white mouse, into other mice, and this gave a tremendous impetus to cancer research in all parts of the world.

The Buffalo Institute obtained some of these transplanted tumor mice and an immense amount of research was done with transplanted tumors. However, it was found that this work was not of great value because we were not really dealing with cancerous individuals, for the mice that received the implant were healthy animals and simply acted as culture media for the growth of tumor cells. Jensen's success stimulated other research workers to try to find spontaneous tumors in mice, that they might establish tumor strains of their own. This led to a search for primary tumors in the stocks of the various breeders of mice and it was soon found that not infrequently, primary tumors occurred in the older mice which were kept for breeding purposes. When we first began looking for spontaneous tumors, we offered a reward of \$25 for each tumor mouse. Soon we had to cut this to \$5 and later to abandon a reward, because of the number that were offered us. The frequency of the occurrence of spontaneous tumors in breeding establishments naturally led investigators to inquire into the origin of these tumors. Careful investigation failed to disclose any apparent extrinsic cause and therefore, the question of heredity suggested itself.

Dr. Marsh, our biologist, mated a male and a female mouse which were the offspring of a cancerous mother, and started a strain of inbred mice for the purpose of observing the effect of this breeding. That particular strain has now reached 20 generations and at present, 94 per cent of the females will have spontaneous cancer of the breast. In another similar strain the incidence is 50 per cent. As these spontaneous tumors do not appear until the middle of the life cycle of the mouse, it was concluded that cancer, per se, is not inherited, but that a tendency to the development of this disease is inherited. Therefore, search was made to find some extrinsic factor which might be the exciting cause.

Much work has been done to determine whether or not trauma could be implicated. Careful examination was made for obvious parasites, such as certain mites, which are known to afflict these animals. However, after long-continued investigation, no apparent relation could be found between these factors and the origin of the tumors. Many ingenious experiments were instituted, such as placing of foreign bodies in the breast, injection of gases and liquids into the ducts, introducing under the skin of mice, parasites

whose normal habitat is on these animals. The results of these investigations were all negative. However, in this work a lead was found which looked promising.

In a certain portion of the colon in white mice, there is found a minute nematode worm, which corresponds to the *Oxyuris* in the human. It was learned by careful counts that this worm was present in large numbers in the mice of high tumor strain, in lessened numbers in the 50 per cent. strain and in still less in wild mice. Sometimes mice of the high tumor strain were found to harbor only a few nematodes. This might explain the non-occurrence of tumors in the 6 per cent. which do not develop them. It has been found by experience that these nematodes do not appear until after the mouse has been weaned. They remain in the colon for 3 or 4 months and then disappear. It was thought that there might be some etiological relation between these nematodes and the origin of the cancer in the breast, for it is a well known fact that nematodes migrate to distant parts of the body. We therefore, devised methods of breeding these mice free from nematodes, by keeping them isolated and in cages through which the droppings could pass. In this way infection by food, which would otherwise become contaminated with fecal matter, was avoided. We have thus far, bred 8 generations free from the nematodes. Mice of the first few generations thus bred, did not show any decrease in the incidence of tumors, but in the later generations, there is a very decided decrease. These experiments are being continued. If we are able to entirely eliminate the tumors, we will then have a tumor free strain. If by again infecting this strain with nematodes we are able to produce tumors, it would appear that there is a definite relation between this worm and the origin of spontaneous tumors in mice.

An interesting fact in regard to these strains of tumor mice is that the male animals, at least in our experience, have never produced tumors in the breast. One might naturally inquire if pregnancy or the suckling of the young has any influence. A series of experiments to answer this question were made, and it was found that the incidence was as great in virgin mice as in those who had borne young. Therefore, the question of nursing apparently does not enter into the problem.

OVARECTOMY

The genital hormone constitutes a marked difference between the male and the female, and experiments were planned to determine the effect of this hormone on the origin of the tumors. It was found that if the mice were ovariectomized before the 20th day, spontan-

eous tumors of the breast did not occur in these animals. However, if this was done at a later date, in other words after puberty had been established, tumors would occur but in somewhat lessened numbers and at a later period in their life. A series of experiments were planned to determine if the origin of the tumors was the result of the ovarian hormone, and male mice were castrated, and injected with ovarian hormone at intervals corresponding to the oestrus cycle. Up to the present, we have never been able to produce a tumor in the male by this procedure. It is probable that the influence of the ovarian hormone is to develop secretory tissue in the breast of the female and it is from this tissue that the cancer originates. The exciting factor associated with secretory disturbances.

PARASITES

Recently there has come from England a report of research work done by Dr. Gye, in which he claims to have been able to cultivate the organism of the Rous chicken sarcoma. I might state that we have done considerable work with this tumor. It is our opinion that this neoplasm differs in many respects from any tumor that occurs in humans or in other animals. Histologically, it appears to be a true neoplasm of the spindle cell sarcoma type. It differs from all other experimental tumors by the fact that it can be propagated by a cell free filtrate. Also by using a dry powder prepared from the tumors successful transplants can be made. In our laboratory we have kept this dried tumor tissue for two years and seven months and then by mixing it with salt solution we have succeeded in producing 100 per cent tumors by injecting it into fowls. Also by taking the blood of chickens dying of the sarcoma, separating the serum and filtering it through a Berkefeld candle, we have been able to produce, with the filtrate, chicken sarcoma in 100 per cent of the fowls inoculated.

Most cancer research workers are agreed that the Rous sarcoma is caused by some agent. However, there is no definite knowledge or agreement as to whether or not this agent is a particulate organism, an enzyme or some chemical substance. Even Rous, who has done the most extensive work with this tumor, is not willing to venture an opinion and speaks of the causative factor as an agent.

For the benefit of those who are not familiar with Gye's work I will give a short summary of it. All men who have worked with the chicken sarcoma, have been baffled by the so-called agent which causes it. Evidently Gye set out to demonstrate the agent and he began, by making cultures from the tumors, using the modern methods. He found that the young

cist and internist and a surgeon. The director has general charge of the activities of the Institute and it is his duty to correlate the activities of the several departments and to stimulate research along various lines.

The Institute is made up of the following departments: pathological, bio-chemical, physical, biological and therapeutic. Each department has its chief with one or more assistants. The chief is responsible to the director for the conduct of the work in his department.

ACTIVITIES

The activities may be roughly divided into routine and research. The routine work consists of, (1) A state-wide free diagnostic service of tissue pathology. This amounts to the examination of between eight and ten thousand specimens yearly. (2) The routine examination and treatment of patients afflicted with malignant disease. These experiments are being continued. If we are able to entirely eliminate the tumors, we will then have a tumor free strain. If by again infecting this strain with nematodes we are able to produce tumors, it would appear that there is a definite relation between this worm and the origin of spontaneous tumors in mice.

An interesting fact in regard to these strains of tumor mice is that the male animals, at least in our experience, have never produced tumors in the breast. One might naturally inquire if pregnancy or the suckling of the young has any influence. A series of experiments to answer this question were made, and it was found that the incidence was as great in virgin mice as in those who had borne young. Therefore, the question of nursing apparently does not enter into the problem.

OVARECTOMY

The genital hormone constitutes a marked difference between the male and the female, and experiments were planned to determine the effect of this hormone on the origin of the tumors. It was found that if the mice were ovariectomized before the 20th day, spontan-

eous tumors of the breast did not occur in these animals. However, if this was done at a later date, in other words after puberty had been established, tumors would occur but in somewhat lessened numbers and at a later period in their life. A series of experiments were planned to determine if the origin of the tumors was the result of the ovarian hormone, and male mice were castrated, and injected with ovarian hormone at intervals corresponding to the oestrus cycle. Up to the present, we have never been able to produce a tumor in the male by this procedure. It is probable that the influence of the ovarian hormone is to develop secretory tissue in the breast of the female and it is from this tissue that the cancer originates. The exciting factor associated with secretory disturbances.

PARASITES

Recently there has come from England a report of research work done by Dr. Gye, in which he claims to have been able to cultivate the organism of the Rous chicken sarcoma. I might state that we have done considerable work with this tumor. It is our opinion that this neoplasm differs in many respects from any tumor that occurs in humans or in other animals. Histologically, it appears to be a true neoplasm of the spindle cell sarcoma type. It differs from all other experimental tumors by the fact that it can be propagated by a cell free filtrate. Also by using a dry powder prepared from the tumors successful transplants can be made. In our laboratory we have kept this dried tumor tissue for two years and seven months and then by mixing it with salt solution we have succeeded in producing 100 per cent tumors by injecting it into fowls. Also by taking the blood of chickens dying of the sarcoma, separating the serum and filtering it through a Berkefeld candle, we have been able to produce, with the filtrate, chicken sarcoma in 100 per cent of the fowls inoculated.

Most cancer research workers are agreed that the Rous sarcoma is caused by some agent. However, there is no definite knowledge or agreement as to whether or not this agent is a particulate organism, an enzyme or some chemical substance. Even Rous, who has done the most extensive work with this tumor, is not willing to venture an opinion and speaks of the causative factor as an agent.

For the benefit of those who are not familiar with Gye's work I will give a short summary of it. All men who have worked with the chicken sarcoma, have been baffled by the so-called agent which causes it. Evidently Gye set out to demonstrate the agent and he began, by making cultures from the tumors, using the modern methods. He found that the young

cultures would successfully produce the neoplasm, but after the culture became several days old it would lose this property. Arguing from the fact that the virus remains viable for long periods in the dried state, it did not seem to him that the organism should die so quickly in cultures. Therefore, he conceived the idea that there must be two factors in the origin of the tumor. The one, the organism, and the other, some other factor which he chose to call a specific chemical substance. Rous found that many antiseptics, among which was chloroform, would kill the agent. Gye made use of this fact in his experiments. He reasoned that in older cultures a chemical substance, which is necessary for the production of tumors, disappears in some manner, but that the agent probably remained viable. He therefore, prepared freshly ground up chicken sarcoma tissue, filtered it and treated it with chloroform to kill the virus. This filtrate supposedly contains the specific chemical substance. He then made cultures from the chicken sarcoma using a special medium. Gye found that if he introduced the chloroformed material into a chicken, no tumor would occur. Also, if he introduced cultures that were several days old, into the chicken, no tumor would occur, but, if he introduced a mixture of equal parts of these, a tumor was produced. In subsequent experiments, by using the chloroformed substance mixed with cultures obtained from other animal tumors, including some from humans, he was able to produce sarcoma in chickens. From these experiments Gye evolved the hypothesis that all cancer is caused by an ubiquitous particulate organism. This, combined with a specific chemical substance, which originates from injured cells, causes tumor formation.

As soon as we learned the details of Gye's work, we undertook to repeat it. In the first place, I might mention that if we carried out Gye's experiments exactly as he did, we obtained similar results. However, we found, that if we treated the ground up tumor tissue with twice the amount of chloroform that Gye used, we were unable to obtain tumors after mixing it with cultures. We also found that if we used the exact amount of chloroform recommended by Gye, but instead of allowing it to stand undisturbed for an hour in the incubator, we agitated the mixture every five minutes or so, that we were also unable to produce tumors by mixing this with cultures. In other words, if we really killed the virus, no tumor could be produced.

As a piece of normal tissue was always contained in the culture media used in making the cultures from the tumors, it was thought that perhaps something in this normal tissue activated the agent which had been stunned by

the chloroform. We therefore, carried on a series of experiments using cultures of chicken embryonic tissue, instead of cultures from tumors, and we were able to produce tumors by this procedure. It is our opinion, deduced from our experience with this research, that Gye's hypothesis cannot be substantiated. I might mention that Dr. Murphy of the Rockefeller Institute has produced tumors in a similar manner by using cultures of placental tissues.

Dr. Kolmer of Philadelphia has reported that he has not been able to demonstrate a specific chemical substance in the chicken sarcoma and that the results of his experiments do not substantiate the conclusions of Gye.

BIOLOGICAL

Warburg of Berlin, has recently reported an interesting piece of research in regard to the biology of the tumor cells. He has found that cancer cells will maintain themselves and proliferate without the presence of oxygen. This is not true of normal adult cells. The energy is obtained by that property, which cancer cells have, of fermenting glucose into lactic acid. Warburg demonstrated this fact by experiments done *in vitro*.

Dr. Cori, the biological chemist of our Institute, substantiated Warburg's work *in vivo*, both in animals and on humans. He inoculated the wing of a fowl, with chicken sarcoma, and was able to analyze the blood going into the tumor and coming out of the tumor, for the relative amounts of glucose and lactic acid. We also had a patient with sarcoma on the arm on whom Dr. Cori was able to perform a similar procedure.

While this work of Warburg's is not of so much importance from an etiological standpoint, it does throw some light on the biological difference between cancer and normal cells. It is apparent that cancer cells contain some enzyme which has the ability of oxidizing glucose into lactic acid and it is thinkable that we may find some substance which may destroy this enzyme in the cancer cells, which as you can readily see, would be of immense value in treatment of this disease.

TREATMENT

The other great problem in cancer research is to find if possible, a successful treatment of malignant disease. We feel that surgery has been perfected and reached its limit and that we can hope for no further advance along this line. Radiation has contributed greatly in the treatment of cancer, radium and X-ray being of value, not only in connection with surgery, but oft times giving results where the patient was past surgical aid. Radiation is quite similar to surgery when used as a caustic and comparable results can be obtained with it when

used on localized lesions The question in research today concerning radiation is to determine if this agent has other effect on the cancer cells, beside the caustic effect If it transpires that radium has a specific action on cancer cells, there is great hope for the future of this agent, for we may find ways and means by which it may be applied to deep seated cancer cells without destroying the normal cells We are carrying on at the present, work aimed to determine, if possible, if radiation has a specific action on immature and malignant cells The problem in the treatment of cancer is to be able to affect deep-seated and metastatic lesions It is evident that surgery cannot accomplish this and if radiation does not have a specific effect upon the cancer cells, our only recourse will be to the intravenous injection of some substance, probably of a chemical nature, which may be carried to these cells by the circulation That there is some hope along these lines is shown by the work of Warburg This work demonstrates that there is a difference in the biology between normal and cancer cells Also in the researches of Wasserman, who found, several years ago, that the intravenous injection of selenium, combined with eosin, would affect cancer cells and not normal cells However, the difference between the fatal dose of this substance upon the normal and cancer cells was so small, that for every mouse that was cured by this method, 9 were killed

Our strains of spontaneous cancer mice offer excellent material for research in intravenous chemical therapy Of course, the choice of chemicals to uses, is purely empirical, as we have no definite lead to follow However, we are at present working with coal tar products, especially the aniline dyes, for they are some of the best known organic chemical compounds While there are several thousands of these, careful analysis shows that there are a greatly lessened number of fundamental ones We have so far worked out about 40 You can readily understand that this is a laborious piece of work, for it necessitates working out the dosage of these dyes on normal animals, before they can be applied therapeutically Our experience to the present, has not led to very gratifying results However, we have learned some interesting facts One of these is the amount of liquid a mouse can tolerate The total amount of blood in a mouse does not exceed 3 cubic centimeters Notwithstanding this, we find that we can inject intravenously, 1 cc of distilled water, every day, for a long period, without causing any apparent discomfort to the mouse Certain dyes which we anticipated would be very toxic, can be given in large quantities without ill effects On the other hand, others were found to be extremely toxic

in minute doses I might say for the benefit of those who have not had experience with the intravenous injection of mice, that the technic is rather ingenious The mouse has two arteries and two veins in its tail By using a simple binocular, it is possible to introduce a very fine needle into the veins However, this procedure is limited, for once the needle has entered the vein, that particular spot often cannot be used again, thus it is necessary to begin at the middle and work towards the root of the tail With good luck we can make from 10 to 14 or more injections on a single mouse After this the medication must be introduced subcutaneously

Recently, Blair Bell of England, has reported more or less success in the treatment of hopeless cancer by the intravenous administration of colloidal lead The use of this substance was suggested to him by the fact that abortions were frequent among lead workers He found that there was some apparent specific effect of lead on chorionic tissue Believing that chorionic cells were comparable to cancer cells, he conceived the idea of trying this chemical on hopeless cancer cases He first used the salts of lead, but finding them to be extremely toxic, he abandoned their use Later he prepared a colloidal solution of lead and fortunately the first case he used this on, showed a remarkable result He has reported in all, about 250 cases These were all advanced cancer and past any benefit from surgery or radiation A few of these cases he claims to have cured and some others offered good palliation When we first heard of Bell's work, we instituted a series of experiments on our primary mouse tumors, to ascertain if colloidal lead, made according to the formula of Bell, would have any beneficial effects on these We have treated a large number of tumor mice with colloidal lead, but have been unable to detect any favorable results In one or two mice having large tumors, there has been a softening of the tumors The contents have been drawn off with a trocar However, at the periphery there were apparently viable cells The animals treated with the lead having small tumors, showed no apparent effect and the tumors continued to grow in the same ratio as those in the control animals We have treated about 20 human cases with colloidal lead, but have seen no favorable results in any of these On the other hand, we have observed a tremendous anemia, the red blood cell count decreasing from 4,000,000 to a million and a half in a period of a week or ten days Autopsies on some of these cases demonstrated a precipitate of metallic lead in the reticulo-endothelial tissue, especially in the liver On the other hand, we were not able to detect the presence of lead in the tumor tissue

EDITORIAL

NEW YORK STATE JOURNAL OF MEDICINE

Published by the Medical Society of the State of New York under the auspices of the Committee on Publication

Business and Editorial Office—2 East 103rd Street, New York, N.Y. Telephone, Atwater 5056

The Medical Society of the State of New York is not responsible for views or statements, outside of its own authoritative actions published in the JOURNAL. Views expressed in the various departments of the JOURNAL represent the views of the writers.

For list of officers of County Medical Societies, see JOURNAL of October 1, 1926, advertising page xxvi.

WINTER ACTIVITIES

The activities of County Medical Societies are somewhat seasonal. Winter is the time of scientific programs, when the evenings are long and the fireside induces thought. Spring is the time for study courses, inspired by the winter's programs. Summer is the season for social gatherings and picnics—activities to be promoted. Fall is the season for the annual meetings of the County Societies, and making plans for the future.

All the year round is the time for sending re-

ports of activities of county medical societies to the New York State Journal of Medicine. But there are meetings of other medical societies—academies of Medicine, hospital staffs, county tuberculosis committees and boards of health—all of which have an interest beyond the restricted circle of their participants, for they tell how a group or community meets concrete problems which will arise in other places.

The columns of this Journal are always open to record items of medical progress.

DR OWEN E JONES

Dr Owen E Jones, President of the Medical Society of the State of New York in 1924-25, passed away on November 18, after a progressive illness of some months. He had been President of his District Branch and active in the Monroe

County Medical Society for years. He was a gifted surgeon and a leader among his confreres. He was of a kindly and retiring disposition, and leaves an example of unselfish devotion to his profession and his friends.

OUR ADVERTISERS

A standard for judging the success of a medical journal is the amount of its advertising. Those who advertise give consideration to two points about a Journal, first, its scientific news and literary appeal to physicians, and second, the response of its readers to the advertisements.

There is abundant evidence that reputable advertisers have watched our Journal with satisfaction. They say that the Journal is excellent, and is the kind of a Journal in which they are pleased to have their names appear. They have a cordial greeting for our advertising manager when he calls.

It is the responsibility of the officers of the Medical Society of the State of New York to make the Journal as good as the best. There is also a responsibility on the members of the State Society to make use of all parts of the Journal. It is a common remark by members that the Journal is good, but that they read only those parts in which *they are interested*. The gynecologist reads the scientific articles on women's diseases, the secretaries of county societies read the reports of their sister organizations, and the health officer reads the reports on public health, but the tendency of each group is to skim over the articles in which the other groups are interested.

The peculiar field of this Journal embraces these topics in which all the members are interested. When doctors converse privately with the officers of the societies, they are eager to learn about activities which they are often surprised to hear are fully reported in the Journal.

The officers and editors have set the standard that everything in the Journal shall be of interest, and that nothing shall be printed merely to fill space. They appeal to the members to read an issue of the Journal from beginning to end, and

note its features. Some members do this very thing with every issue, and it is their commendations which inspire the editors and officers to put forth renewed efforts to raise the Journal to still higher standards.

Two concrete applications of these remarks may be made.

First, the book reviews are real news items concerning the newer medical publications, and are excelled by those of no other publication in their interest and comprehensiveness. Anyone reading a review will find it to be the disinterested opinion of the physician whose name is signed to it. These opinions are valued by every publisher, for he can thereby ascertain what the doctors want to buy, and the physician will be stimulated to buy those books which will be useful to himself. A physician will be well repaid by turning to the book review department of every issue of the Journal.

Second, as to the paid advertisements, every one of which conforms to the high standards of the American Medical Association. The advertisements tell the physician where he can secure high class instruments and books and service. The advertising pages are guides to reliable manufacturers, sanatoria, medical schools, laboratories, and services which every doctor must employ. Every advertisement has more than a financial appeal to the doctor. That it is an index to the services which doctors wish, is shown by inquiries regarding firms whose advertisements have appeared in past issues of the Journal.

The object of this editorial is to call the attention of physicians to features of this Journal in which they would be deeply interested if they should look for them.

COUNTY HEALTH OFFICERS

There is only one county health officer unit in New York State—that in Cattaraugus County—but Tompkins, Suffolk and other counties are considering their establishment under the provisions of the Public Health Law. A county health unit consists of a board of health, a health officer, and such employees as may be authorized by the Board of Supervisors. The local boards of health and health officers remain as at present,

but the local health officers become deputies of the county health officer. The line of distinction between the county health officer on the one hand and of the local health officer, on the other, are not defined in any hard and fast way. Dr Paul B. Brooks, Deputy State Commissioner of Health, has made the following suggestions in an unofficial way, with the expectation that the health officers themselves shall arrange the details of

the division of their respective activities and relations

"Broadly speaking, the county health officer should accept responsibility in the following

1 Inspection of dairies and collection of milk samples This work should be done by an inspector with sufficient training and experience, such an inspector being an essential part of any county health organization Milk dealers' permits probably should be issued by the county health officer who is comparatively independent of local influences often embarrassing to the local health officers

2 Inspection of camps, boarding and maternity homes, the permits to be issued by the county board of health

3 Investigation of nuisances affecting more than one municipality, the action with reference to abatement to be taken by the county board of health Investigation of other major nuisances on request of the local health officers, the action with reference to abatement to be taken either by the local or county board of health

4 Investigation and control of communicable disease outbreaks affecting more than one municipality, assisting local health officers in the control of local outbreaks

5 Collection of epidemiological data and formulation of plans for the prevention of communicable disease outbreaks

6 A county health officer naturally would

promote various county-wide projects such as county laboratory service, toxin-antitoxin immunization, tuberculosis clinic service, etc.

7 The county health officer should visit all local health officers periodically for the purpose of familiarizing himself with the details of their work and advising and assisting them, calling them together as often as practicable and necessary for conference He should maintain intimate contacts with all practicing physicians, and through the county medical society—of which he should be an active member—and through his personal contacts endeavor to interest them not only in the public health projects but in practicing preventive medicine privately

8 The county health officer should conduct a continuous educational campaign, furnishing news and other articles to local newspapers, one purpose being to stimulate people to go to their own physicians for periodic health examinations, immunization against diphtheria, and other preventive treatment and advice He should endeavor to make some provision for the furnishing of such service to people unable to pay

Dr Brooks does not try to list the duties of the local health officer, for they are too numerous to warrant enumeration The local health officer should perform all the duties required of him by law which are not to be performed by the county health officer and such additional duties as may be imposed upon him as a deputy by the health officer "

PROFESSIONAL STANDARDS IN OPEN HOSPITALS

The maintenance of a high standard of medical and surgical services is a serious problem in open hospitals, especially those of the smaller communities, where every physician in the neighborhood has the privileges of all the services A patient entering any hospital has a right to expect to receive the best treatment which the community can afford—and this means that of the best physicians available in that section in any particular line If the hospital is approved by the American College of Surgeons, so much the stronger will be the implication that its standards are high in every line of treatment

When any branch of medicine is considered, nearly every community has some one doctor who excels his brethren in that particular line, even though he does not rank as a specialist If this man were consulted when a case of his specialty comes into the hospital, the problem of standards would be solved But the human equation is always to be considered There are the likes and dislikes of both the doctor and the patient, and an appealing manner and a smooth tongue must always be balanced against scientific skill

The problem of standards has two aspects 1, that relating to patients unassigned to any par-

ticular doctor, and 2, that relating to private patients

Appointments for the care of free or ward patients are usually given in rotation to doctors willing or desirous of filling the positions The system results in the choice not of the *one* best man, but of the *three* or *four* best—which necessarily lowers the average standard of the hospital

The question often arises whether or not the hospital authorities can have any control over a doctor in his treatment of his own private cases An overwhelming professional sentiment is developing that every physician who uses a hospital shall be subject to its rules and standards This means that he shall keep accurate records of his cases and his treatments, and shall permit their review and discussion by other members of the staff The day is past when a hospital patient is the private property of a doctor to be treated as he may wish Every doctor must conform to standards of which his associates are the judge The question of standards comes up the most frequently in connection with surgery, where skill and ultimate results are clearly open to all observers Who shall be permitted to operate? Shall any doctor who has the courage to operate

on an appendix be allowed to do so? This is an example of problems of standards which confront the governing boards of every open hospital

How shall authorities of a hospital settle the problem of standards of professional service? Possibly it would be better to ask how they may raise the standards, for no hospital can attain one hundred per cent of perfection in its standards and ideals. Two suggestions offer themselves

1 The appointment of a chief of staff in each department, medical, surgical, obstetrical, after the manner of the great city hospitals

2 Each department shall appoint a small committee which shall oversee the work of that department and judge it according to accepted standards. The advantage of this method is that the committee need not be composed of specialists, for any physician can judge the qualifications of a specialist and the results that he produces. Such a committee is well able to judge of the qualifications of a doctor who aspires to do major operations in surgery, and can dictate the con-

ditions under which he may operate. It might say, for example, that Dr. X may operate on a case of appendicitis if he will do so under the supervision of Dr. Y, who is known to have skill

The essential qualifications of the members of a supervising committee are stability of character, good judgment, and wise diplomacy. Every community has numbers of doctors who are credited with those virtues by the unanimous consent of their professional brethren

The execution of the plan of committee control of professional work will not be easy. After the consent of the doctors has been secured, the plan must be adopted by the board of trustees, and often by a third body—the women's visiting committee. Possibly the difficulty of securing the necessary cooperation makes the plan seem visionary. But in reply the question may be asked, "Who can judge and control standards of professional work in hospitals better than a representative group of the physicians who compose its staff?"

HYGEIA

The American Medical Association, representing the medical profession of the United States, has adopted the policy of educating the public in medical subjects, and it further leads the way by publishing *Hygeia*, a monthly medical journal for laymen. *Hygeia* has grown steadily in popularity and influence and its value is indicated by the frequent quotations which appear in the newspapers. It is a typical journal to place on the table of the doctor's waiting room, and on the reading table of every school and library

Physicians who are making their lists of Christmas gifts may well include *Hygeia*. A present of this journal will be especially welcome to school children who are compelled to study

hygiene and to undergo physical examinations by doctors and inspections by nurses. *Hygeia* will tell them what it is all about. The Journal is well illustrated and each number contains pages for small children. But *Hygeia* also carries many pages of more serious matter which is of wide interest to grown people

LOOKING BACKWARD THIS JOURNAL 25 YEARS AGO

The following report of the Committee on Publication for the first ten months of this Journal's existence is taken from page 308 of the December 1901 issue

"The publication of the Association's journal—the New York State Journal of Medicine—was begun in January of the present year. A copy has been mailed each month to every member of the Association. Including the October number, 31,800 copies have been distributed. In addition a supplement was issued with the May number. Forty-six original papers were presented at the last annual meeting of the Association. The manuscripts of forty-four of these have been published

The expense connected with the monthly publication of the Journal, naturally, is of considerable interest. The estimated cost of twelve issues, ending with the December number, is \$1,950. From this is to be deducted the net receipts from advertising contracts, amounting to \$888, which reduces the total to \$1,068. The average net cost of each issue of the Journal, therefore, will be \$89. These figures compare very favorably with those connected with the publication of Volume XVI of the Association's Transactions, issued one year ago. The cost of 1,000 copies was \$1,633.99, which included printing, binding and delivery, of approximately \$1.64 per volume.

MEDICAL PROGRESS

Treatment of Local Infection—In an article in *Physical Therapeutics* for October, 1926, (xliv, 10) William Benham Snow considers infections associated mainly with pyogenic processes rather than types of infection found with serious constitutional symptoms from the outset. The value of hyperemia as a therapeutic agent is well established. It accelerates elimination, phagocytosis, and the tissue-producing processes in the body. The practical means of producing hyperemia which are available and valuable are reflected radiant light and heat from a suitable electric arc or incandescent bulb or bulbs, dry hot air, applied with suitable apparatus, and diathermy from a high frequency transformer. When surgeons cease to use hot moist dressings, which at best give only the effects of convective heat, with hyperemia in the skin only, the heat being carried away with the circulation without affecting the cellular tissues beneath the skin, and when they adopt the use of dry heat from the outset, they will have satisfactory results. An experience of twenty-five years with dry heat has demonstrated that this agent arrests the infectious process in all early cases, without fail. If an infection is detected within twelve hours, by the appearance of a persistent red spot, one or two hours' application of radiant light projected over the spot, as hot as can be tolerated, will terminate the trouble. Diathermy is especially indicated in the treatment of acute and subacute appendicitis, sinusitis, pneumonia, bronchitis, and pleurisy. The application is made with the same rules as in other types of heat administration, being limited to skin toleration. In infections about the face and head reflected radiant light is most valuable. Otitis media can be promptly relieved by the use of reflected incandescent light, the application being made for one hour daily until the discharge ceases. In acute cases paracentesis is not performed, light is applied twice daily for an hour each time. The ear recovers its normal condition in seven to ten days, which is a more favorable result than from paracentesis. Radiant light is effective in purulent and gonorrheal ophthalmia, and in erysipelas it has proved most satisfactory. In a large number of cases of erysipelas seen by the author there was no instance in which it failed to afford relief. One patient in *extremis* with septicemia following a surgical operation three weeks previously, showed a remarkable improvement after thirty minutes in the hot air apparatus, as evidenced by the skin hyperemia, temperature, and pulse,

and in ten days was convalescent. In the treatment of internal conditions diathermy is usually employed in conjunction with the x-rays. Heat, the r-rays, and ultraviolet light play an important rôle in the management of a class of cases which have been more or less neglected, and they may effect a cure such as has not been possible by other means.

Intercostal Neuralgia From Visceral Disease—M. Lapinsky does not regard intercostal neuralgia as an independent primary affection nor does he see sufficient causal relationship between it and such general conditions as hysteria, neurasthenia, and anemia. He believes it to be due to visceral lesions and in the present article deals with the rôle of lesions in the lesser pelvis, including the external genitals. Of two cases reported one in a woman was traced to appendicitis and cystic degeneration of the right ovary, while the other case in a man depended on an orchitis and funiculitis. The author finds many brief references in literature to the occurrence of radiating pains in disease of the lesser pelvis and a special tendency for pain to be reflected to the thorax, although authors seem to be silent in reference to intercostal neuralgia *per se*. Naturally there must be mechanisms to explain such cases, but the author does not even allude to the Head zones, and in any case these would not account for cases like his own, for in the second case the neuralgia was on the side opposite to the lesions. He also omits any reference to zoster of the intercostal nerves and its dependence on visceral disease, although the two subjects have much in common. In his opinion the anatomy of the sympathetic nervous system, while naturally asymmetrical because of the asymmetry of the viscera, is further subject to much individual variation which may explain the general want of type in these cases and the absence of general laws.—*Archiv f Psychiatrie*, Sept 18, 1926 (vol lxxviii, Nos 1-2).

The Abdominal Crises of Pernicious Anemia.—Hamilton Bailey, writing in the *British Medical Journal*, Sept 25, 1926, No 3429, refers to the fact that the gastric crises of tabes may closely simulate the symptoms of perforated gastric ulcer, and the mistake has been made of operating on these patients. It is not so well known, however, that pernicious anemia in its later stages may occasionally be complicated with abdominal crises. The resemblance

of the symptoms to those of the "acute abdomen" are so close that even the most conscientious surgeon may be trapped. The ghastly pallor of the patient, especially in artificial light, is mistaken for that of profound shock or internal hemorrhage, and when this picture is combined with a history of sudden agonizing abdominal pain and vomiting, and is accompanied by abdominal rigidity, the difficulty in diagnosis is occasionally insurmountable, unless one is in possession of the knowledge that the patient is the subject of an aplastic anemia. The explanation of the abdominal attack seems to be that during the catabolism of large numbers of erythrocytes the liver is called upon to excrete a prodigious amount of bile pigment. This is too concentrated to be held in solution and is precipitated in the form of "bile mud," which gives rise to severe biliary colic. This theory is supported by the findings in one of the two cases which the writer reports. In this case a diagnosis of gastric ulcer was made and laparotomy performed. The gall-bladder was found enormously distended, and when opened was found to contain thick black "biliary mud." In the second case the color index of the blood was taken and gave the typical reading for pernicious anemia, no operation was performed and the acute symptoms subsided.

Abdominal Pain in Children in Extra-abdominal Conditions—Alton Goldbloom says it is well known that abdominal pain is a rather common complaint in children, who are apt to refer any pain to the abdomen (*Canadian Medical Association Journal*, October, 1926, xvi, 10). Instances of moderate abdominal pain at the onset of a throat infection are in some epidemics extremely common, and are met with in influenza, measles, and scarlet fever. It is hardly conceivable that all these cases can be explained by the suggestion of Brennermann, namely, that an inflammation of the abdominal lymphatic nodes exists coincidentally with the throat infection, and therefore the pain has its origin in true intra-abdominal disease. It is more reasonable to infer that the abdominal pain is merely a remote echo of the trouble in the upper respiratory tract. Cases of throat infection, in which abdominal pain is encountered, can be divided into two groups. In the first, and by far the largest, group the pain is the first and the outstanding symptom, it is rarely accompanied by tenderness and almost never by rigidity. In these cases the pain subsides before the signs of the throat infection and there is no diagnostic difficulty. In the second group the pain occurs after the onset, and sometimes after the subsidence, of the throat infection, and tenderness,

rarely rigidity, is a feature. These cases could well fit with Brennermann's explanation of adenitis. In cases of intrathoracic disease, the abdominal symptoms may predominate, as with lower lobe pneumonia or with diaphragmatic pleurisy. Abdominal pain may also occur with right apical pneumonia and in empyema. Such cases are cited by the writer. The various pathways by which nerve impulses could be transmitted and interpreted as abdominal pain are discussed.

Alkalies in the Treatment of Functional Albuminuria—According to H. Meden it is only recently that we have learned the power of alkalies to reduce the amount of albumin in the urine of albuminuria, and von Hoesslin was the first to announce the fact although apparently his finds were not beyond criticism. Thus he realized that only in functional albuminuria does albumin disappear completely, while in the albuminuria of nephritis it can merely be reduced. In regard to functional albuminuria the generalization held good for the orthostatic, athletic, and other known causal types, as well as for those in which no cause was discoverable. The author has for the past two years been checking up the finds of von Hoesslin in the medical polyclinic service of Charité Hospital, Berlin, and has had opportunity to test 27 patients with albumin in their urine. Five were frankly nephritic and in this small material he obtained no reduction in the amount of albumin excreted by the use of alkalies. In the other and larger series of 22 patients, in whom no evidence of structural renal disease could be obtained by the usual tests, he was able to clear up the urine in all but four, merely by giving them a heaping teaspoonful of sodium bicarbonate three times a day, apparently with no adjuvant measures. Of the four exceptions three were found to be febrile tuberculosis patients and he was obliged to conclude that the disease had in some way attacked the integrity of the renal tissue. The fourth exceptional patient was apparently quite resistant to the alkali although no cause could be assigned. The author comments on the strangeness of the find, for physicians are used to giving alkalies in renal and other urinary abnormalities and often an attempt is made to get rid of the trace of albumin, as in insurance work, yet no one seems to have made this discovery until recently—*Zeitschrift für klinische Medizin*, Oct. 12, 1926 (vol. civ, Nos. 1-2).

Syphilitic Gastric and Duodenal Ulcers—Bernales and Bambaren of Lima report a series of seven cases of peptic ulcer seen over an interval of three years. The patients all recovered or

MEDICAL PROGRESS

Treatment of Local Infection.—In an article in *Physical Therapeutics* for October, 1926, (xliv, 10) William Benham Snow considers infections associated mainly with pyogenic processes rather than types of infection found with serious constitutional symptoms from the outset. The value of hyperemia as a therapeutic agent is well established. It accelerates elimination, phagocytosis, and the tissue-producing processes in the body. The practical means of producing hyperemia which are available and valuable are reflected radiant light and heat from a suitable electric arc or incandescent bulb or bulbs, dry hot air, applied with suitable apparatus, and diathermy from a high frequency transformer. When surgeons cease to use hot moist dressings, which at best give only the effects of convective heat, with hyperemia in the skin only, the heat being carried away with the circulation without affecting the cellular tissues beneath the skin, and when they adopt the use of dry heat from the outset, they will have satisfactory results. An experience of twenty-five years with dry heat has demonstrated that this agent arrests the infectious process in all early cases, without fail. If an infection is detected within twelve hours, by the appearance of a persistent red spot, one or two hours' application of radiant light projected over the spot, as hot as can be tolerated, will terminate the trouble. Diathermy is especially indicated in the treatment of acute and subacute appendicitis, sinusitis, pneumonia, bronchitis, and pleurisy. The application is made with the same rules as in other types of heat administration, being limited to skin toleration. In infections about the face and head reflected radiant light is most valuable. Otitis media can be promptly relieved by the use of reflected incandescent light, the application being made for one hour daily until the discharge ceases. In acute cases paracentesis is not performed, light is applied twice daily for an hour each time. The ear recovers its normal condition in seven to ten days, which is a more favorable result than from paracentesis. Radiant light is effective in purulent and gonorrheal ophthalmia, and in erysipelas it has proved most satisfactory. In a large number of cases of erysipelas seen by the author there was no instance in which it failed to afford relief. One patient in *extremis* with septicemia following a surgical operation three weeks previously, showed a remarkable improvement after thirty minutes in the hot air apparatus, as evidenced by the skin hyperemia, temperature, and pulse,

and in ten days was convalescent. In the treatment of internal conditions diathermy is usually employed in conjunction with the x-rays. Heat, the r-rays, and ultraviolet light play an important rôle in the management of a class of cases which have been more or less neglected, and they may effect a cure such as has not been possible by other means.

Intercostal Neuralgia From Visceral Disease.—M. Lapinsky does not regard intercostal neuralgia as an independent primary affection nor does he see sufficient causal relationship between it and such general conditions as hysteria, neurasthenia, and anemia. He believes it to be due to visceral lesions and in the present article deals with the rôle of lesions in the lesser pelvis, including the external genitals. Of two cases reported one in a woman was traced to appendicitis and cystic degeneration of the right ovary, while the other case in a man depended on an orchitis and funiculitis. The author finds many brief references in literature to the occurrence of radiating pains in disease of the lesser pelvis and a special tendency for pain to be reflected to the thorax, although authors seem to be silent in reference to intercostal neuralgia *per se*. Naturally there must be mechanisms to explain such cases, but the author does not even allude to the Head zones, and in any case these would not account for cases like his own, for in the second case the neuralgia was on the side opposite to the lesions. He also omits any reference to zoster of the intercostal nerves and its dependence on visceral disease, although the two subjects have much in common. In his opinion the anatomy of the sympathetic nervous system, while naturally asymmetrical because of the asymmetry of the viscera, is further subject to much individual variation which may explain the general want of type in these cases and the absence of general laws.—*Archiv f Psychiatrie*, Sept 18, 1926 (vol lxxviii, Nos 1-2).

The Abdominal Crises of Pernicious Anemia.—Hamilton Bailey, writing in the *British Medical Journal*, Sept 25, 1926, No 3429, refers to the fact that the gastric crises of tabes may closely simulate the symptoms of perforated gastric ulcer, and the mistake has been made of operating on these patients. It is not so well known, however, that pernicious anemia in its later stages may occasionally be complicated with abdominal crises. The resemblance

versity of Freiburg, assisted by Vorländer and Jung, publishes a serial article on this subject in the *Muenchener medizinische Wochenschrift*, September 17 and 24, 1926. In the opinion of Opitz cancer is both a local and general disease. It is known that numerous substances have affinity for the tumor cell—we are positive in the case of iodine and reasonably certain for a number of metals and dyes—so he is not at all surprised that occasional cures follow the internal use of arsenic, selenium, copper, gold, lead, cerium, iron etc., either alone or in some combination. Non-specific protein therapy also seems to give positive results at times. Cancer is commonly recognized as having to do with some anomaly of metabolism and at present the opinion is that in place of an oxidation of the glucose a lactic acid fermentation results, which produces a local acidosis favorable to tumor growth and a reduced demand for oxygen. Cholesterin is regarded as a growth stimulant, lecithin as an inhibitor. The authors believe it possible to find a substance or plan of treatment which will cause a metaplasia of the highly toxic cancer cell into a more innocent type of epithelial cell. Recently they have tried out various sulphur combinations on the supposition that the tissues are lacking in sufficient sulphur, and also injections of glucose which exert a specific action in causing the disappearance of the tumor-glycogen while the same substance in normal tissues is undisturbed. Some of the indications, in addition to inhibiting cell growth or causing metaplasia, are removal of the acidosis by alkalization and restoration of metabolism to normal end-products. The authors have been unable to influence animal cancer permanently by means of eosin and selenium, cholin and others of the older tumoraffin substances.

The Treatment of Varicose Veins by Injection—The necessity for an efficient non-operative treatment of varicose veins is emphasized by the increasing number of quack remedies advertised in the lay press. The only treatment short of operation recognized in standard works on surgery lies in mechanical support. These facts led A. H. Douthwaite (*British Medical Journal*, September 25, 1926, ii, 3429) to experiment with the production of thrombosis in varicose veins by the method of Genevrièr. The solution used is composed of quinine hydrochloride, 4 grams, urethane, 2 grams, and distilled water 30 cc. A pneumatic tourniquet is applied with moderate pressure above the portion of the vein to be dealt with, and 0.25 cc. of the solution is injected into the lumen through a fine hypodermic needle. Perivenous administration is usually unnecessary, it is not, however, contradicted, provided only a few minims are introduced outside the vein. The puncture is

sealed with collodion, which may be removed the same night, and the injection repeated about two inches further up the vein. With very large varices the same areas may have to be injected two or three times. As a rule, however, one injection is sufficient for each two or three inches of vein treated. The author has treated 88 unselected cases of varicose veins in this way, with success in every instance, and no recurrences have as yet been observed. The thrombosis appears to be firm and adherent, and in a series of over a thousand injections has never given rise to embolic disturbances.

The Hashish "Jag"—E. Jöel and F. Frankel have been studying the action of five drugs from a relatively new angle, namely that of psychology and the psychoses. We now have a special branch of research under the name of pharmacopsychology which deals with drug intoxications as transitory psychoses or, as Kraepelin calls them, "insanity in miniature." The five drugs referred to comprise ether, cocaine, mescaline, kava kava, and hashish, but in the present article only the latter is discussed. One of the authors took the drug and the other studied the objective behavior while the experimenter also recorded his subjective sensations. Ten centigrams of a strong English extract caused after a short time a sensation of strangeness, of something inescapable, of foreboding, while weakness and anxiety replaced the normal sensations, and activity went into abeyance. One may give up to it or fight it, and if the former a perfect torrent of ideas, thoughts of old events which often had passed out of remembrance, unusual sensations, and emotional reactions beset one. These seem quite outside of the subject's ego and volition. Later there is a series of pictures and from the unconscious there well up experiences long forgotten. They may awaken interest, pleasure, laughter, or only pain and weariness. All of the experiences are compulsive, proceeding from without, and the subject may believe himself hypnotized or under the control of some other person. Every variety of psychopathology is experienced—illusions, splitting of personality, disturbance of time and space relations, and there is every shade and stage of consciousness represented. The complicated ego or personality is disintegrated and abstract logical thinking goes back to an archaic-prehistoric stage in which there is only a succession of images, as in dream states. We obtain new glimpses into myth and mysticism. There are several clinical types—the motor, delirious, and paranoid.—*Klinische Wochenschrift*, Sept. 10, 1926

improved under diet and antisyphilitic treatment. In at least five patients the lues was hereditary. The symptoms of pain and vomiting were marked and in four of the cases gastrorrhagia was prominent as a symptom. One patient had been subjected to gastroenterostomy after a diagnosis of ordinary peptic ulcer, his lesion suggesting a recurrence, this is the only case in which the authors were not certain of their diagnosis. Of the authors quoted who have reported similar cases the great majority are Latins—French, Italians, and South Americans. There are a few Germans but neither English nor Americans figure. It may or may not be only a coincidence that only one of the seven patients was of pure white blood, the others being Indian or, mostly, halfcastes. Of the seven, five presented gastric and two duodenal ulcers. To take one case at random, the third in order, the patient was a half breed Indian of 31 who had complained for the past two years. History of chancre at 21. His symptoms had been limited at first to pyrosis, flatulence, and pain with later supervention of hematemesis and melena. Pain developed within an hour after taking food. Aside from his indigestion his condition was fair. Reduction in the number of red cells may have been due to hemorrhage. The Wassermann was frankly positive and a diagnosis was made of syphilitic gastric ulcer. The bismuth picture suggested an obstruction at the pylorus. There was gastric retention of 45 cc only. The acidity was increased. The only treatment mentioned was a course of neosalvarsan, and atropine for the excess of acid. The patient remained in the hospital only about a month, after which he left of his own accord with all symptoms improved.—*Revista de la Sociedad de Medicina Interna*, July, 1926.

Experimental Superinfection of Human Syphilis—T Hashimoto, professor in the Japanese University at Mukden has inoculated twenty human subjects already known to be syphilitic with secretions containing spirochetes taken from chancres, papules, pustules, and gummata and with tissues containing the same organisms which were implanted in the skin. The spirochete was not actually demonstrated in the matter from pustules and gummata. In order to distinguish between living and dead cultures control inoculations were made at the same time with the same matter sterilized by heat. The lesions produced showed great variability but the author feels himself justified in asserting positively that superinfection of a syphilitic at any stage is in general possible, though there may be individual exceptions. The author differs from others who have worked in this field for he finds no correspondence between the character of the lesion produced by inoculation and the stage of the syphilis of the inoculated subject. There were

negative results in some of the cases and the author makes three types of positive results, the frankly positive, weakly positive, and incomplete, the latter being apparently non-specific. The inoculated subjects were naturally untreated during the period of experiment. Spirochetes were readily found in the inoculation lesions. The experiments of the author do not appear to differ in essentials from older work in the same direction but the viewpoint is not the same. The older experimenters studied the possibility of reinfection, the phenomenon of allergy of the skin, the possibility of transmission of tertiary syphilis, etc., while the author appears to limit his research purely to the problem of superinfection—*if a man is already frankly syphilitic can he be made more syphilitic?* The answer apparently is in the affirmative under certain circumstances.—*Bruxelles Médicale*, September 12, 1926.

The Symptom Complex of Hypotonia, Including Low Blood Pressure—Martini and Pierach attempt to outline this type of constitution in an article which appears in the *Klinische Wochenschrift* for September 24 and October 1, 1926. The organs to show the principal alterations, which are mostly functional, comprise the heart, blood vessels, abdominal musculature, and skin. The tone is relaxed with reduced efficiency. There are also anomalies of function in the organs of internal secretion, probably all of them, and of the vegetative nervous system. The picture of suprarenal insufficiency is occasionally striking. The authors believe that the muscles and nerves which are not under the control of the will are the ones involved in this habitus. The somatic picture associated with this functional one is the familiar asthenic habitus. One of the most striking characteristics of hypotonia is low blood pressure. One might anticipate that this type of constitution is a pure liability, but in the authors' opinion the reverse is the case. According to Barach the hypotonic is essentially long lived, which is borne out by statistics of large insurance companies of the United States. Thus while the actual mortality of all risks is 80 per cent of the expected, for patients with habitually low blood pressure it is but 35 per cent. It seems probable that the hypotonic does not live as fast as the average, his metabolism is slower, he conserves his vital energy better. In the clinic the hypotonic usually appears masked with some organ-system weakness which dominates the picture, especially digestive disturbances. He derives considerable benefit from substances which raise the blood pressure (caffeine) and from internal secretions—thyroidin, pituitrin, gonad extract, etc.

Recent Progress in Cancer Therapy—Professor Opitz of the chair of gynecology, Uni-

as to make it imperative that any physician accused shall be apprised fully and clearly of the wrong or dereliction of which he is accused and shall be given a full and complete opportunity to be heard in his own defense, either personally or by counsel or both. Any accuser, therefore, contemplating the preferment of charges against a physician, should bear these provisions in mind and should not proceed until he has been able to reduce to writing a clear statement of what the charges are and until such accuser shall have prepared himself or itself to sustain the charges, when called upon to do so, by competent legal evidence. No matter what the physician's dereliction may have been, the accuser need not hope to succeed unless he is able to reduce to writing a statement of what the charges are and unless he is prepared to sustain those charges by competent proof when called upon to do so. Ill-considered or half-considered charges lacking a proper foundation or not supported by the requisite evidence must be foredoomed to failure.

Disciplinary Powers of the Component County Medical Societies—Each component county medical society is governed by its constitution and its by-laws. In general the disciplinary powers of the component county medical societies may be divided into two branches: (a) the power to discipline its members and (b) the power to exclude from membership those unqualified for membership. As to the right to discipline its members, it should be remembered that the extent of the jurisdiction of such societies runs only to the censure, suspension or expulsion of the member from the Society. No county medical society has the power in itself to revoke a physician's license. For the particular powers of each county society, its constitution and by-laws should be carefully studied and scrupulously followed. The provisions of each, though all are similar in purpose and general effect, vary in phraseology. For the purposes of illustration the provisions of the By-Laws of the Medical Society of the County of New York in this respect are worthy of brief attention.

By Chapter VIII, Article 3 of those by-laws, the censors of the New York County Medical Society are given power to "take cognizance of all charges preferred against a member. Charges against a member shall be presented to the President in writing, and by him referred to the censors, who shall meet, examine the same and the evidence thereon."

Article 4 declares that "If the majority of the censors shall be of the opinion that the charges are well founded, they shall serve a copy of them upon the accused and call for his attendance on a given date before the censors

Of this meeting the accused shall have at least ten days' notice. At the time and place appointed, the accused shall be required to make answer to the said complaint, either in writing or verbally, and the censors shall proceed to a hearing of the case upon such charges and the answer thereto, and if no answer be interposed, upon the complaint alone. The censors may call as witnesses any member of the Society whose duty it will be to obey such summons and any member failing to obey a summons of the Board of Censors, without a satisfactory excuse, shall be liable to discipline." Article 5 of Chapter VIII reads "There shall be three degrees of discipline: censure, suspension and expulsion."

It is further provided that after the hearing of the charges the censors shall report their findings to the Comitia Minora at its next meeting. The Comitia Minora shall then consider the report, and if it finds the charges proved, it may censure or suspend the accused as in its judgment the offense demands, but if in its judgment the offense demands expulsion it shall recommend such action to the Society at a Stated Meeting. A three-fourths vote of the members present and voting, shall be necessary for expulsion."

Running through these provisions and qualifying them at every point are the essential requirements that the accused shall know what the charges against him are and shall have the right to be heard in his own defense and that he cannot be censured, suspended or expelled from the county society unless those essential rights are accorded to him in good faith and in a manner that is in conformity with full and complete justice. Provisions similar to these should be found in the by-laws of all of the various component county medical societies.

As to the power of the county society to exclude an unfit applicant from membership, again recourse may be had to the provisions of the By-Laws of the New York County Medical Society for the purposes of illustration. These are contained in Chapter XII of these By-Laws.

Article I of this chapter provides that "The Committee on Membership shall investigate and report on applications for membership received from the Secretary."

Article 2 provides that this Committee "shall meet within five days previous to each stated meeting of the Comitia Minora for the consideration of such applications for membership as may have been placed in its hands by the Secretary. Before reporting favorably upon any application for membership, the Committee shall be satisfied, by proof deemed sufficient by it, that the applicant has complied with the laws of the State of New York relative to the

DISCIPLINARY POWERS AND FUNCTIONS OF THE STATE AND COUNTY SOCIETIES

There is no subject of greater importance to the medical profession and to the laity than the power to discipline erring members of the profession. This has long been recognized in the sister profession of the law and the grievance committees of the various bar associations have performed notable work in holding lawyers to a high standard of professional conduct and also in protecting their good names against unjustifiable attack.

The need for the statutory regulation of these powers with respect to doctors was recognized by the last legislature in its enactment of Chapter 834 of the Laws of 1926, by which a grievance committee was instituted and given statutory sanction. But certain disciplinary powers still reside in the various component county medical societies and in the State Medical Society. We shall therefore consider the subject of disciplinary powers from three aspects: first, the powers and duties of the statutory "Committee on Grievances", second, the disciplinary powers of the various component county medical societies, third, the disciplinary powers of the State Medical Society.

Powers and Duties of the Committee on Grievances—The statutory committee is given jurisdiction "to hear all charges against duly licensed physicians of this state" for the following shortcomings:

(a) Where a physician is guilty of fraud or deceit in the practice of medicine or in his admission to the practice of medicine,

(b) Where a physician has been convicted in a court of competent jurisdiction, either within or without this state, of a crime or misdemeanor,

(c) Where a physician is an habitual drunkard, or addicted to the use of morphine, cocaine or other drugs having a similar effect, or has become insane,

(d) Where a physician is guilty of untrue, fraudulent, misleading or deceptive advertising, or advertising that he can cure or treat disease by a secret method, procedure, treatment or medicine or that he can treat, operate and prescribe for any human condition by a method, means or procedure which he refuses to divulge upon demand to the Committee on Grievances,

(e) Where a physician undertook or engaged in any manner to procure or to perform any criminal abortion.

The power of the grievance committee extends to the revocation, suspension or annulment of the practitioner's license and to other discipline in accordance with the statute. Before the grievance committee can exercise any of these powers, the following conditions must have been complied with:

(a) Charges must have been preferred against the physician. These charges may be preferred by "any person, corporation or public officer" and they must be filed with the Secretary of the Committee on Grievances. The charges must contain a plain and concise statement of the material facts without unnecessary repetition, but not the evidence by which the charges are to be proved. It is a fundamental principle of justice which lawyers have long described by the term "due process of law" that no person can be deprived of his rights without being clearly apprised of the nature of his delinquency and the manner and respect in which he has transgressed and has been given an opportunity to be heard in his own defense.

(b) After charges have been received by the Grievance Committee, the accused must be given an opportunity to appear either personally or by counsel at the hearing, with the right to produce witnesses and evidence upon his own behalf, cross-examine witnesses and to "examine such evidence as may be produced against him and to have subpoenas issued by the said committee."

The powers then, of the statutory grievance committee, are separate and distinct from the powers of the various county medical societies or of the State Medical Society. It is a public body organized to hear and determine charges against any physician preferred by "any person, corporation or public officer." Thus any citizen has a right to prefer these charges. This language is so broad as to enable a component county medical society or the State Society itself to prefer the charges in any case.

While the powers and duties of the statutory grievance committee have not as yet been construed by the courts, there is no doubt that the courts, when called upon, will so construe them.

as to make it imperative that any physician accused shall be apprised fully and clearly of the wrong or dereliction of which he is accused and shall be given a full and complete opportunity to be heard in his own defense, either personally or by counsel or both. Any accuser, therefore, contemplating the preferment of charges against a physician, should bear these provisions in mind and should not proceed until he has been able to reduce to writing a clear statement of what the charges are and until such accuser shall have prepared himself or itself to sustain the charges, when called upon to do so, by competent legal evidence. No matter what the physician's dereliction may have been, the accuser need not hope to succeed unless he is able to reduce to writing a statement of what the charges are and unless he is prepared to sustain those charges by competent proof when called upon to do so. Ill-considered or half-considered charges lacking a proper foundation or not supported by the requisite evidence must be foredoomed to failure.

Disciplinary Powers of the Component County Medical Societies—Each component county medical society is governed by its constitution and its by-laws. In general the disciplinary powers of the component county medical societies may be divided into two branches (a) the power to discipline its members and (b) the power to exclude from membership those unqualified for membership. As to the right to discipline its members, it should be remembered that the extent of the jurisdiction of such societies runs only to the censure, suspension or expulsion of the member from the Society. But certain disciplinary powers still reside in the various component county medical societies and in the State Medical Society. We shall therefore consider the subject of disciplinary powers from three aspects: first, the powers and duties of the statutory "Committee on Grievances", second, the disciplinary powers of the various component county medical societies, third, the disciplinary powers of the State Medical Society.

Powers and Duties of the Committee on Grievances—The statutory committee is given jurisdiction "to hear all charges against duly licensed physicians of this state" for the following shortcomings:

(a) Where a physician is guilty of fraud or deceit in the practice of medicine or in his admission to the practice of medicine,

(b) Where a physician has been convicted in a court of competent jurisdiction, either within or without this state, of a crime or misdemeanor,

(c) Where a physician is an habitual drunkard, or addicted to the use of morphine, cocaine or other drugs having a similar effect, or has become insane,

(d) Where a physician is guilty of untrue, fraudulent, misleading or deceptive advertising, or advertising that he can cure or treat disease by a secret method, procedure, treatment or medicine or that he can treat, operate and prescribe for any human condition by a method, means or procedure which he refuses to divulge upon demand to the Committee on Grievances,

(e) Where a physician undertook or engaged in any manner to procure or to perform any criminal abortion.

The power of the grievance committee extends to the revocation, suspension or annulment of the practitioner's license and to other discipline in accordance with the statute. Before the grievance committee can exercise any of these powers, the following conditions must have been complied with:

(a) Charges must have been preferred against the physician. These charges may be preferred by "any person, corporation or public officer" and they must be filed with the Secretary of the Committee on Grievances. The charges must contain a plain and concise statement of the material facts without unnecessary repetition, but not the evidence by which the charges are to be proved. It is a fundamental principle of justice which lawyers have long described by the term "due process of law" that no person can be deprived of his rights without being clearly apprised of the nature of his delinquency and the manner and respect in which he has transgressed and has been given an opportunity to be heard in his own defense.

(b) After charges have been received by the Grievance Committee, the accused must be given an opportunity to appear either personally or by counsel at the hearing, with the right to produce witnesses and evidence upon his own behalf, cross-examine witnesses and to "examine such evidence as may be produced against him and to have subpoenas issued by the said committee."

The powers then, of the statutory grievance committee, are separate and distinct from the powers of the various county medical societies or of the State Medical Society. It is a public body organized to hear and determine charges against any physician preferred by "any person, corporation or public officer." Thus any citizen has a right to prefer these charges. This language is so broad as to enable a component county medical society or the State Society itself to prefer the charges in any case.

While the powers and duties of the statutory grievance committee have not as yet been construed by the courts, there is no doubt that the courts, when called upon, will so construe them.

cietly shall also cease to be a member of this Society "

Section 46 gives the Board of Censors of the State Society "jurisdiction to hear and determine all appeals from decisions on discipline of component county medical societies or decisions of such societies which may involve the privileges, rights or standing of members whether in relation to one another or to the county medical societies or to this Society Any member of any component county medical society, feeling aggrieved by the decision of such society, may within three months after such decision *appeal to the Board of Censors of this Society* from the decision of such component county medical society by filing a notice of appeal with the Secretary of this Society and the Secretary of the component county society "

Section 47 provides that "any applicant for membership in a component county medical society who may have been excluded from membership in such society, may likewise appeal from the action of said Society excluding him All decisions shall be subject to appeal to the House of Delegates "

Section 48 provides that "The notice of appeal shall set forth in writing the name of the applicant, the name of such component county medical society and the date and substance of the decision appealed from, *and shall indicate the ground or grounds upon which such appeal is taken* "

Section 49 provides that "Upon filing a notice of appeal, the appellant and the component county medical society shall submit to the Secretary of the Board of Censors *all records, minutes, letters, papers and all written evidence including a digest of all testimony not stenographically reported relating to the matter* All data so submitted shall be confidential and privileged and shall be available only to the censors and on appeal, to the members of the House of Delegates "

Section 50 provides that "The Board of Censors shall consider the appeal on the data so submitted to it, and may affirm by a majority vote, modify or reverse by a two-thirds vote of the Censors present and voting, the decision so appealed from. *If, in its opinion, the taking of further testimony is advisable, the Board of Censors may summon witnesses and proceed to take such evidence in such manner as it may deem proper* and render its decision by a two-thirds vote of those present and voting, *which decision shall be binding until reversed or modified by the House of Delegates* "

Section 52 provides that "A party desiring to appeal to the House of Delegates from the decision of the Board of Censors shall, within

three months after such decision, file with the Secretary of this Society and the Secretary of the component county society a notice of appeal Such notice of appeal shall set forth in writing the name of the appellant, the name of the component county society, the date and *substance of the decision appealed from and the ground or grounds upon which such appeal is taken* "

Under Section 54 the House of Delegates is required to "consider and decide the appeal on the data submitted to it, and may affirm, modify or reverse the decision so appealed from Such decision of the House of Delegates shall be final and binding "

But even after the House of Delegates has affirmed the decision of the Censors, under general provisions of law the appellant would doubtless still have the right to a further review in the courts

Thus a person disciplined by a competent county medical society or excluded from membership therein has the right of appeal—first to the Censors of the State Society, second to the House of Delegates and finally to the courts These rights indicate and explain the necessity of having the records upon which action is taken in proper, complete and ample form This requirement would exist in the absence of specific provisions of the by-laws, but such provisions are clearly stated within the by-laws themselves, for it is provided that upon an appeal to the Board of Censors of the State Society, the county society which has acted upon the individual in question must submit "*all records, minutes, letters, papers and all written evidence including a digest of all testimony not stenographically reported relating to the matter* " In order to sustain its action, therefore, it is of the highest importance that each component county medical society should follow this requirement and should not act hastily or without adequate legal proof It should be prepared, when an appeal is taken from its decision, to substantiate its decision by evidence "The records, minutes, letters, papers and all written evidence including a digest of all testimony not stenographically reported" should be such as to substantiate, justify and support the action taken While the Board of Censors of the State Society has the power upon appeal to take further evidence and to summon witnesses, this does not relieve the particular county society involved from the burden of preparing and submitting upon the appeal, the evidence upon which its decision is based in such a way as to obviate the necessity of taking further proof The county society should be prepared, upon such appeal, to have its counsel or other representative present to explain and justify the

practice of medicine, and that such applicant is of good moral and professional character, standing and reputation, and that his admission would not be prejudicial to the best interests of the Society"

Article 3 requires that "The Committee shall make its report to the Comitia Minora at each meeting of the Comitia Minora"

Article 4 requires that "The Committee on Membership shall file with the Secretary of the Society *its reasons* for unfavorable action upon any applicant for membership"

These provisions and similar provisions of the other component county medical societies must receive a full, liberal and fair interpretation

A county medical society is not in the nature of a social club. The purpose of each of the county societies in general may be said to be that of regulating the practice of medicine and surgery and of aiding in securing the enforcement of the laws relating thereto and of contributing to the diffusion of true science, particularly the knowledge of the healing art, and to assist in the preservation of the public health. Thus, no county medical society would be justified in excluding an applicant from membership through mere whim or caprice, as might be done in the case of a purely social organization

The requirements for membership in the New York County Medical Society (continuing to use that as an example), are that the applicant must establish, by proof deemed sufficient by the Comitia Minora, that he "is of good moral and professional character standing and reputation, and that his admission would not be prejudicial to the best interests of the Society" Thus, good moral and professional character, standing and reputation are made essential qualifications for admission. The added requirement (found in the New York County By-Laws), that these facts of "good moral and professional character, standing and reputation" must be established by proof deemed sufficient by the Comitia Minora, must receive a liberal and fair and not a strained interpretation. The provision does not mean that the Comitia Minora is given the right to be arbitrary in its decision, to act upon mere whim or caprice. The interpretation that the courts would undoubtedly give to these words would be, not that the Comitia Minora might arbitrarily determine that the essential facts have not been established in a manner "deemed sufficient by it," but that they have not been established in a reasonable manner and in such a way as would be deemed

sufficient by a reasonable man. Every physician in good standing has, or should have, a laudable desire to become a member of his county medical society and, by virtue of this, a member of the State Medical Society. Membership in the latter carries with it important rights, among which are the right to legal defense in the event of the institution of an action for malpractice, and the right to take advantage of the liberal provisions of the group plan of insurance. These rights, therefore, should not be denied arbitrarily and without adequate cause and sufficient reasons. On the other hand, no physician whose moral or professional character, standing and reputation are not good, should be admitted to membership in these honorable bodies. The admission committees, therefore, of the various county societies have important functions to perform. They must, on the one hand, do justice to the applicants and on the other hand do justice to the Society and to the profession. When, therefore, an admission committee is of the opinion that the application of a given applicant should not be favorably acted upon, it should take the time and pains to ascertain and establish the definite facts upon which its conclusion has been reached, it should not act upon hearsay alone or upon a mere vague opinion that the applicant is an improper person, it should have definite, concrete and convincing reasons for its action and should prepare, collect, collate and preserve the evidence upon which those reasons have been based. Aside from the obligation to do justice, a further reason for this will be apparent when we consider the powers of the State Society.

Disciplinary Power of the State Medical Society—Section 1 of the State Society's by-laws provides that "The active members shall be members in good standing of the component county medical societies"

Section 2 provides that "Any member suspended or expelled from a component county society shall likewise be suspended for the same period or expelled from this Society. Any member suspended or expelled from this Society shall likewise be suspended for the same period or expelled from a component county society. His right of appeal to this society shall not be impaired nor shall such appeal prevent the carrying out of the judgment of the county society pending such appeal. Any member not in good standing in his county society shall not be a member in good standing in this Society, and any member ceasing to be a member of his county so-

NEWS NOTES

THE FIRST DISTRICT BRANCH

The First District Branch held its annual meeting on the afternoon of Wednesday, November 10, in Briarcliff Lodge, Briarcliff Manor, Westchester County. The attendance of 110 was the largest in the history of the Branch.

While the members were assembling, the opportunity was offered for visiting and forming acquaintances. Dr Arnold Jackson who had come from the Jackson Clinic in Madison, Wisconsin, to address the meeting, told a group how his grandfather had originated the clinic when he and his son, both surgeons in the Civil War, returned from the army and began the practice of medicine together in Madison. The son associated himself with other doctors in the group practice of medicine, and when his five sons had grown, he formed the organization known as the Jackson Clinic. Four of the sons are physicians and the fifth is the business manager of the institution.

The corporation in its present form was organized in 1910, and now employs 21 physicians each of whom is a specialist in some subject. The clinic has its own rooms and nursing staff, but while it does not maintain a hospital, the members of its staff are on the staffs of hospitals of the city and some are teachers in the University of Wisconsin.

Most patients at the clinic are referred to it by their family doctors. They are examined thoroughly by the several specialists of the staff, and after all needed laboratory tests are made, the patient is either referred back to the family doctor, or is sent to a hospital and put under the care of a member of the clinic.

Dr Jackson said that the plan of group practice was popular in the Middle West and that over 200 clinics similar to this had been organized. A regular meeting of an organization of representatives of the clinics in one section of territory had recently been held in his clinic, and a general meeting of all the clinics was held once a year.

Physicians in the East know of the group practice mainly through the clinics of the Mayo brothers and Dr Crile, and it is rather surprising that the plan is seldom adopted in the Eastern states.

The presence of Dr Edwin H Huntington, an obstetrician at Ossining, recalled original researches of his grandfather and great grandfather which resulted in the recognition of the form of mental derangement known as Huntington's chorea. The Huntingtons of the first and second generation had practiced medicine for seventy-

five years in Easthampton, Long Island, where the intimate history of every inhabitant was known from the days of founding the settlement in 1647. The members of the old families had intermarried for reasons largely financial, and thereby had intensified their hereditary characteristics. The father and son had preserved accurate records of about twenty cases of the disease which were presented by the grandson as his thesis on graduating from the College of Physicians and Surgeons in 1871.

The grandson, Dr George Huntington, practiced medicine successfully in Le Grange near Poughkeepsie. He avoided a city because he suffered intensely from asthma and was frequently incapacitated for weeks at a time.

A business session of the Branch was called to order about noon, and the following officers were elected for two years beginning at the close of the annual meeting of the State Society.

President, Dr Edward R Cuniffe, Bronx, First Vice-President, Dr George B Stanwix, Yonkers, Second Vice-President, Dr Charles D Kline, Nyack, Secretary, Dr Ralph O Clock, Pearl River, Treasurer, Dr John T Howell, Newburgh.

The members dined together at 12 30, and then assembled for a scientific session which lasted until 5 o'clock.

The first address was given by Dr N B Van Etten, of the Bronx, on the subject "The antiphtheria campaign in New York State." Dr Van Etten represents the Medical Society of the State of New York in the general committee composed of members drawn from all the public health organizations of the state. He reviewed the work accomplished throughout the state and urged the doctors to give toxin-antitoxin to the children of the families whom they treat.

The guest of the session was Dr Arnold S Jackson, of the Jackson Clinic, Madison, Wisconsin, who presented a paper on "The Diagnosis and Treatment of Diseases of the Thyroid Gland." Dr Jackson gave a simple, clear description of the varieties of goiter, and outlined the treatment. He also showed lantern slides of cases and made running comments which tended to fix the points which he developed in his paper.

Dr Jackson has consented to the publication of his paper in an early issue of this Journal.

The other numbers on the program were "The Obstetrical Case—Some new Developments," by Dr Alfred M Hellman, New York, discussion by Dr Wm P Healy. "Intra-cranial Hemorrhage in the Newborn" by Dr William Sharp.

action of the county society and to produce witnesses in support of its action should the Board of Censors deem such a course necessary or advisable

Running through all these provisions is the essential requirement that no person can be deprived of his rights without "due process of law"—without a full opportunity to be apprised of the charges against him and an opportunity to meet them on the merits

It is hoped that the foregoing discussion may clarify the situation in such a way that when the Board of Censors of the State Society is called upon to act on an appeal, it may do so in such a way as to do justice both to the accused and to the county society in question. Hasty or ill-considered action will tend only to defeat the proper aims, purposes and ideals of the medical profession of this State

TONSILLECTOMY—LUNG ABSCESS

The plaintiff in this action, a trained nurse about twenty-five years of age, was first seen by the doctor on March 31st, having been referred to him by another physician, with a history of frequent colds and some coughing. An examination disclosed that she was suffering from a low-grade bronchitis. By means of suction it was ascertained that there was pus in the tonsils. After the examination the doctor advised the performance of a tonsillectomy, which was done on April 29th under a general anaesthesia of ether. The tonsils were removed intact and the throat carefully examined by the doctor, his assistant and the nurse. The anaesthetist was one of the female staff of anaesthetists of the hospital, who had been trained and graduated from the hospital's course on anaesthesia. During the operation suction apparatus was applied continuously. There was no abnormal amount of bleeding.

Owing to a lung condition, the patient remained at the hospital a longer period of time than the normal after an operation of this nature. While at the hospital she was seen twice by the doctor.

About three weeks after the operation she telephoned the doctor that she had a cough. He referred her to the physician who had first attended her. About two months thereafter she reentered the hospital with a diagnosis of lung abscess. Upon her reentry into the hospital she was under the care of other physicians. She was immediately put to bed but was later placed on the sun porch. The doctor who performed the tonsillectomy did not attend or treat the patient at this time, except that he examined her throat and found it in good condition. She was thereafter examined by several physicians, who expressed a doubt as to the presence of a lung abscess. X-rays were taken and upon examination of the same it was believed that there was a lung abscess. The roentgenologist in interpreting the plates reported the condition as

bronchial pneumonia. The doctor had been advised by her attending physician that her temperature was normal and she was getting along very well. Upon the second occasion on which the patient was in the hospital, she remained for a period of about ten days or two weeks.

About nine months after the tonsillectomy the surgeon who performed the same was sued in an action of malpractice in which the complaint charged the performance of the operation on April 28th and that shortly thereafter, while the patient was suffering from the effects of the operation, she became afflicted with a long abscess and that the same was due solely to the negligence and carelessness of the defendant in the performance of his operation, in that he did not use the proper care, appliances and skill in operating upon the plaintiff.

During the pendency of this action the plaintiff took the deposition of a witness who was a former nurse at the hospital and was then residing in a foreign state. By this witness the plaintiff attempted to show that the defendant physician was negligent and careless in the selection of the anaesthetist and that the nurse who had administered the anaesthesia to the plaintiff was incompetent and unqualified to act as such. The plaintiff also, in her endeavor to establish a cause of action against the plaintiff, examined the defendant before the trial.

When the action was about to come on for trial the plaintiff's attorney sought to procure a settlement, first for a substantial sum, and when his efforts in that direction were unsuccessful, he then asked for a nominal sum, asking that some settlement be made so that at least he could be compensated for his services. All of his efforts with respect to settlement being a failure, he then consented to the discontinuance of the action and an order was entered to that effect.

of the A M A, and that a truthful account of his life could be written within five minutes, if occasion requires

These are some of the impressions that a visiting editor acquires in a brief visit to the building of the American Medical Association. But the object of the conference of secretaries and editors, more than the inspection of the building and the activities of the American Medical Association, was to enable the visitors to exchange information which they could apply in their home work in their own states. The conference was like the meetings of the secretaries of the county medical societies held in New York State early in the fall. As the reports of work done were presented by the several secretaries, the New York delegation noticed that the variance of conditions in the several states was equal to that in the counties in New York State, and that what was adapted to our state might not be suited to another. Still there was much of universal application, and something novel and good was likely to emanate from the small states as frequently as from the large ones. It might even be said that the smaller states had the advantage in originating new ideas, for they did not have to contend with the inertia of numbers and precedents.

Since a full account of the conference will be printed in the A M A Bulletin in the near future, probably the January number, only impressions of the more striking points will be given here.

The conference was opened with an address by our own Dr Wendell C Phillips, President of the American Medical Association. He was followed by Dr Daniel S Dougherty, Secretary of New York State Medical Society, who told of the organization and work of the District Branches and of the possibility of their development. Dr Dougherty later told of the organization of the Medical Society of the State of New York and how the Society conducts its business. His address will appear in the A M A Bulletin.

Dr Morris Fishbein told his opinion of some State Medical societies based on his visit to six, in which New York State was not included. The representative from Illinois said that all the district meetings of his state discussed four topics, (1) how to improve the organization, (2) what should be the minimum standard of a county society, (3) scientific service and supplying speakers for programs of county societies, and (4) lay education on medical topics, especially the enlistment of local talent in speaking and writing.

Dr Jabez H Jackson, of Kansas City, President-elect of the American Medical Association, gave a pleasing address on State Society activities. He spoke especially of the medical education of the public, and said that in Kansas City

a school was started in order to train doctors to speak to lay audiences. Twenty-five doctors were enrolled for a two weeks' course. Each doctor prepared an address which was criticized by a professor from the State University. The doctor then delivered it and the professor of the class discussed it and made suggestions for its improvement. One great object of the instruction was to get the doctor to make his remarks simple so that the lay audience could follow his ideas.

Dr Jackson illustrated his idea of how a doctor should address an audience by recalling an old book on etiquette which he bought when he started to make society calls. The book said that the way to make a good impression on a lady was to start a conversation on some topic that she likes, and when she becomes interested, to pick up his hat and go home. The time for a doctor to quit talking to a lay audience is while the listeners are still keenly desirous for more information. Don't spoil a good speech by making it too long.

Dr George Edward Follansbee, of Ohio, described the model constitution of state societies suggested by the special committee of the A M A. Several representatives of State Societies reported having adopted it with excellent results. Its provisions seem to be covered by the constitution of the New York State Society.

The part of the State Journal in medical organization was happily discussed by Dr F A Long, Editor of the Nebraska State Journal. He said that his Journal required the full time of the editor for one week in every month, and he advocated a paid editor for every State Journal. He used small news items, such as marriages and vacations, to interest the readers. His editorial pages were an open forum to which from two to four doctors were invited to contribute each month. He gave space to the women's auxiliary society. He supplied three cuts free to authors. A rather curious remark was that books were reviewed for only those publishers that advertised in the Journal.

Dr O S Wightman, Editor-in-chief of the *New York State Journal of Medicine*, described the policies and departments of the *New York State Journal of Medicine*. He was followed by Dr Gallagher, of Tennessee, who gave a rather doleful description of the difficulties of the editor of a journal of a small state. On the other hand, Dr C A Ray, of West Virginia, gave a glowing report of the growth of his state society when the dues were raised from four dollars to twelve, and the State Journal was made attractive in appearance and contents, especially in emphasizing the activities of the county societies.

Dr Bowers, Editor of the *Boston Medical and Surgical Journal*, said that the Journal was the oldest in the country and would reach the cen-

of New York, discussion by Dr E R Cunniffe, Bronx "Post Influenzal Disturbances of the Heart," by Dr Albert S Hyman, New York,

discussion by Dr O S Wightman, New York. It is expected that these papers will be published in this Journal

THE ANNUAL CONFERENCE OF STATE SECRETARIES AND EDITORS OF STATE JOURNALS

The annual conference of the Secretaries of State Medical Societies was held on November 19 and 20, in Chicago, Illinois, in the building of the American Medical Association, under the auspices of that organization. The editors of the State Medical Journals were also present and took part in the discussion. The representatives from the Medical Society of the State of New York were, Dr D S Dougherty, Secretary of the Society, Dr Orrin S Wightman, Editor-in-chief of the *New York State Journal of Medicine*, and Dr Frank Overton, Executive Editor.

The conference afforded the opportunity for meeting the leaders of the American Medical Association and the state representatives, many of whom have been attending the conferences for fifteen or twenty years and have taken an active part in developing the modern methods of medical society activities. It is both gratifying and inspiring to form the personal acquaintance of doctors who are known by their broad reputations, and especially to experience the friendliness and personal helpfulness of Dr Olin West, the Secretary and general manager of the Association, and of Dr Morris Fishbein, Editor of the *Journal of the American Medical Association*. The whole spirit of the conferees, both in and out of the meetings, was that of fraternity and equality.

The conference revealed the immensity and broadness of the work of the American Medical Association. The officers of the Medical Society of the State of New York, appreciating the importance and complexity of the task of keeping in touch with the medical societies of sixty counties, can comprehend the still greater work of leadership over the fifty constituent societies of the national body.

The physical plant of the American Medical Association is imposingly great. While one is not impressed with the size of the building itself, he begins to appreciate the greatness of the A M A as he views the long rows of offices, and is informed that the building houses about 400 employees. One is impressed still more when he inspects the printing plant, in which the ten publications of the Association are printed. It is a large piece of work to print the Journal, each issue with its 87,000 circulation and 150 pages. This is made possible by presses which use rolls of paper instead of sheets, and curved stereo-

typed plates instead of flat reciprocating forms. The printing facilities of the A M A are among the best in the whole country, and are exceeded by few establishments in New York State. The editors of the State Journals can fully appreciate the convenience and efficiency of having a complete printing plant always available and instantly accessible.

The great majority of physicians of the United States get their principal impression of the American Medical Association through its Journal, which is published weekly. Editors who have to get out monthly or semi-monthly journals can appreciate the amount of work required to prepare weekly issues of a Journal of the size and scope of that of the A M A. About two weeks' time are required for the preparation of each number, and before an issue is mailed, the forms for the succeeding issue are fully prepared. Each week the number of pages is determined and the departments in which the articles have a general interest regardless of the exact date of their appearance are assigned places in either the front or the back part of the Journal, leaving the center pages for news articles and others of a timely nature so that they may be set up at the last possible moment. Editors will appreciate the fact that necessity enters into the choice of the location of an article or department.

A visitor to the editorial offices is also impressed with the varied nature of the information that is carried by the Journal. Whence come the obituaries of doctors throughout the nation? A group of clerks sort newspaper clippings supplied by commercial bureaus throughout the country. From the same source come many of the news items that occupy the center of the Journal. Then there are the reports on new remedies which are supplied by the research department of the A M A. There is the information regarding quacks and medical frauds, which is quoted from the department which collects information regarding them and files sets of their literature and information regarding their promoters. Then there are departments which file lists and biographies of all doctors in the United States, all those licensed by state boards, and all medical students. It may gratify the pride of any doctor to know that all essential information regarding him is carefully preserved in the files.

THE NEW YORK ACADEMY OF MEDICINE

The new building of the New York Academy of Medicine at 2 East 103rd Street, New York City, was formally opened with a dinner given in the Waldorf Astoria on the evening of Wednesday, November 17th, to the twenty-two newly elected honorary fellows, and by appropriate addresses and a reception on the afternoon of Thursday, November 18, in the new building.

The Wednesday evening dinner was attended by over one thousand physicians and guests. Dr Samuel A. Brown, President of the New York Academy of Medicine, was Chairman, and Dr George David Stewart was toastmaster. Addresses were given by the Honorable James J. Walker, Mayor of New York, and by three of the newly made Honorary Fellows: Dr Harvey W. Cushing, Surgeon-in-Chief of Peter Bent Brigham Hospital, Brookline, Mass., Dr George de Schweinitz, Professor of Ophthalmology, University of Pennsylvania, and Dr William Sidney Thayer, Professor of Medicine, Johns Hopkins University.

The ceremonies of the formal opening of the new building on Thursday afternoon were held in Hosack Hall in the new building. Dr Samuel A. Brown, President of the Academy, described the service of the Academy in medical progress, Dr Arthur B. Duell, Chairman of the Building Committee, told the history of the new building and equipment. The diplomas of the Honorary Fellowships were given to those recipients who were present, and the citations of their accomplishments were read.

Following the formal exercises a reception and inspection of the building was held during which the rooms and corridors overflowed with members and their guests. A collation was also served.

In the evening the first meeting in the new

building was held, when Dr Michael I. Pupin, of Columbia University, gave the Carpenter lecture on the subject "Ionization and Chemical Reactions." Dr Pupin's address was a model of clearness and simplicity, and made plain a subject in which an audience usually becomes lost after hearing a few paragraphs.

All the addresses given during the ceremonies will be published in the *Monthly Bulletin* of the Academy.

The new building of the New York Academy of Medicine is spacious and conveniently arranged, and is in keeping with modern progress in medicine. The first floor contains an information desk, reception rooms large and small, and the main hallway to Hosack Hall, the large assembly room. The second floor contains section meeting rooms, and the hallway to the balcony of Hosack Hall. The third floor is given over to the Library and a reading room for the Fellows. A mezzanine floor also contains eight rooms for bibliographical research. The fourth floor contains section meeting rooms and the general offices of the Medical Society of the State of New York. The fifth floor contains the rooms of the New York State Journal of Medicine, and the New York County Medical Society. The sixth floor contains the administration offices of the Academy, and the rooms of the Public Health Relations Committee and the Bureau of Clinical Information.

Visiting physicians will be welcomed and calls for information will be answered, especially those regarding clinics and teaching facilities in Greater New York. The telephone of the Academy is Atwater 4700. The building is easily reached by the Lexington Avenue subway to 103d Street and by the Fifth Avenue busses.

DINNER TO DR. DOWNING

The dinner to Dr Augustus S. Downing, Assistant Commissioner of Education and Director of Professional Education of New York State on December 9 in the Hotel Commodore, New York, will have a two-fold object, first, as a memorial to the passage of the Medical Practice Act last spring, and second, in honor of the Commissioner who promoted the law with all the force of his character and position. Every physician in New York State will wish to hear Dr Livingston Farrand, Dr Nicholas Murray Butler, and Dr Wendell C. Phillips give radiant expression to the thoughts which he vaguely feels.

The following appeal has been made by those

who have served Dr Downing as medical examiners.

"The undersigned, during their period of service with the New York State Education Department were in daily touch with Dr Augustus S. Downing, Assistant Commissioner in charge of Professional Education. They learned to recognize him as a true servant of the state, continuously and indefatigably applying himself to endeavors which would inure to the benefit of the people through the medium of the professions. In his task he favored no friends and feared no enemies. Where standards were below the yardstick of accepted educational measurement, he

tury mark in 1928. He described some of the details of carrying on his Journal, which is a weekly.

Dr Bulson of Indiana, made a plea for the support of the A M A and for the freedom of action by the editor. "Get the right man" he said, "and then give him free and scope for his activities." But the doctor did not refer to the other side of the problem, that the wise editor would like to have some person or committee who should share the responsibilities of the publication.

Dr D F Sullivan, Secretary of the New Hampshire Medical Society, read a paper entitled "How can we secure closer cooperation with other professions and with the laity?" He described a meeting of the New Hampshire Medical Society which was held in connection with a conference of health officers, and meetings of lay public health organizations, thus making an assemblage of practically all the health forces of the state. The Medical Society had secured Dr Charles Mayo for one of its speakers, and had invited laymen to hear his address. Although the subject was a medical one, laymen said they were surprised that they could understand and enjoy him. He quoted this as a concrete example of cooperation with other organizations.

The discussion which followed centered around a single cooperating profession, that of nursing. Dr Wightman opened the discussion by suggesting the need for more helpers for the sick, rather than highly trained girls whose function is that of carrying out those doctors' orders which require great skill. A training of six months, or a year, should fit a girl to attend to the ordinary bodily needs of a sick person, and that was about all that was required in most cases of sickness. This plan was supported by several other speakers.

Dr W G Ricker, who presided as chairman of the conference, said that New York State was not improving the nursing situation in his home state of Vermont because the representatives of the New York State Examiners of Nurses were discouraging the training schools by refusing to recognize their graduates on grounds which he deemed insufficient.

The program of the closing session was de-

voted largely to periodic health examinations. Dr John M. Dodson, Executive Secretary Bureau of Health and Public Instruction of the A. M. A. said that 61,000 copies of the manual of the A. M. A. had been distributed to doctors, of which 51,000 had been sent through twenty-four State Medical Societies. There had also been distributed 295,000 copies of the examination form.

Dr Dodson also discussed the attitude of Life Insurance Companies toward the examinations of applicants and the insured. While some companies were trying the experiment of accepting applicants without a medical examination, others were offering annual examinations free to policy holders. The John Hancock Company was trying the experiment of sending a policy holder to his own family physician for an examination, and paying the doctor five dollars and at the same time not asking for a report on the insured, the theory being that a policy holder who takes the trouble to be examined by his own physician will follow the doctor's advice.

Dr Dodson thought that the principal stimulus to urge the people to take the examinations should come from departments of health.

Dr Wightman called attention to the fact that people are going to clinics for periodical examinations, and will do so in increasing numbers unless doctors prepare themselves to make better examinations than the clinic doctors do.

The representative from Wisconsin said that the State Society had sent twenty-five leading doctors to present the subject of periodic examinations to the county medical societies.

The most original suggestion came from the Oregon representative who proposed the formation of a national college of periodic medical examiners modelled after that of the American College of Surgeons. It was planned that the condition of membership should be the filing of 100 complete examinations. He said that the scheme was actively promoted by the Oregon State Medical Society.

The conference was a great success, because the seventy-five participants were practical men who filled their positions because of their love of the work and their adaptation for doing it.

WOMEN'S MEDICAL CENTER

An invitation is extended by the Women's Medical Association of New York City to all of the Medical women of the city and state of New York, to discuss and take action upon the proposal to form a Medical Center for women physi-

cians in New York worthy of the Empire State.

The meeting for organization will be held at The Women's University Club, 106 East 52nd Street, New York City, at 8 o'clock, December 1, 1926.

an inmate in a state hospital I did not know that at the time, but thought his answers to my questions very peculiar I left the tubes with the brothers, after having explained about them As the cultures were to be taken for three successive days, this meant that I had to return for them I had knocked off the oil pan under my car, by the boulders in the middle of the road which I had no way of avoiding After three days, I

went in a Ford, accompanied by the Health Officer, after the tubes The Ford traveled the road much better than my car I have just received a letter from the Health Officer, saying that Albany has requested more cultures from these people I am not a pessimist, but I am of the opinion that after this rainy weather the most suitable conveyance would be either an aeroplane or else to go by horseback"

BRONX COUNTY MEDICAL SOCIETY

A regular meeting of the Bronx County Medical Society was held at Concourse Plaza, on October 20, 1926, at 9 P M, with the President, Dr Cuniffe, in the Chair

The following candidates were elected Alexander J Habersack, Benjamin Karen, Hyman L. Rachlin, Frederick W Schaeffer

The Secretary presented the Report of the Nominating Committee Action will be taken at the Annual Meeting

The Chairman of the Committee on Legislation presented the Report of the Committee. He expressed the opinion that Governor Smith has done more for the medical profession than any previous Governor, and suggested the adoption of resolutions endorsing the Governor for re-election

The Chairman of the Building Committee reported regarding the recent developments and plans for a Home for the Society

The Chairman of the Committee on Public Health and Medical Education reported regarding the subject of Periodic Health Examinations The moving picture to be shown tonight is the first of the demonstrations the committee intends to present to the Society so that the doctor may have a full understanding of what is expected of him

A regular meeting of the Bronx County Medical Society, held at Concourse Plaza, on November 17, 1926, was called to order at 9 P M, the First Vice-President, Dr Louis A Friedman, in the Chair

Dr Friedman expressed the regrets of Dr Cuniffe at not being able to preside at this meeting on account of being invited to represent the Bronx County Medical Society at a Dinner given in celebration of the formal opening of the new building for the New York Academy of Medicine

Election of candidates being in order, it was moved and carried that the Secretary be instructed to cast one ballot for the following candidates for membership Joseph S Hory, Vincent C. Hughes, Martin I Kirschner, Moses Kopel, Leiber W Lerner, Joseph Nack, Della M Weintraub

in connection with these examinations The committee is working in conjunction with the Bronx Tuberculosis Committee on the matter of Periodic Health Examinations

The Chairmen of the Committees on Collection Agency and Medical Economics presented the reports of their respective committees

Resolutions endorsing the Honorable Alfred E Smith for re-election as Governor of the State of New York were approved by the Society

Resolutions of sympathy on the death of Dr Samuel J Littenberg were approved

Resolutions of sympathy on the death of Dr Mendel Zagat, ex-President of the Bronx County Pharmaceutical Association, were approved

A motion picture, "He Who Laughs Last," was presented, demonstrating the technique of periodic health examinations

The Scientific Program proceeded as follows

1 Radiography in Obstetrics (with lantern slides) Drs Hyman J Epstein and Abraham J Fleischer.

2 Pathological Conditions of the Cervix and Their Treatment. Dr Frederick C Holden

3 The Importance of Splanchnoptosis in Gynecology Dr Harry Aranow

Dr Friedman, for the Committee on Public Health and Medical Education, reported with particular reference to the subject of Periodic Health Examinations

Dr Lukin, for the Committee on Medical Economics, reported progress

Dr Jacobs, for the Building Committee, reported progress

It was moved and carried that the President appoint a Committee to consider the question of the establishment of a Relief Fund

The officers for 1927 suggested by the Nominating Committee at the October meeting were unanimously elected

A resolution was passed in memory of Dr Matthew S Goldman, recently deceased

This meeting having been designated as an Economic Meeting, the program proceeded as follows

strove for the desired uplift and knew no pause until the result sought had been accomplished

"Early in his career he recognized the shortcomings of the Medical Practice Act as it admitted of unsatisfactory effects, both to the public and to the medical profession. He planned to strengthen the law, thus to obviate its defects. For this purpose he outlined his program to those interested and in the face of forceful opposition both in the profession and among legislators, year after year he battled for what he believed would be a proper statutory adjudication of the items in dispute. He had had similar experiences in connection with the affairs of most of the other professions and because of his unswerving devotion to all that pertained to the ethical status and to the uplift of these various other groups, legislators, regardless of political affiliations, grew to know him as an altruist and they respected him accordingly, relying upon his judgment as to matters pertaining to his official duties.

"And so, when last year Dr. Downing once again appealed to the legislators and to the Governor in behalf of the bill sponsored by the Medical Society of the state, in spite of a centralized and coordinated opposition employing every method known to the lobbyist, the authorities enacted into law the present statute. The fight for the law has been won—the task of enforcing it is now delegated to those who will need the support of the profession. The outstanding figure in this effort has been Augustus S. Downing.

"The members of the medical profession, to-

gether with the members of the allied professions through a designated Committee, are planning to display a measure of their appreciation of Dr. Downing's valuable services to the state by giving a dinner in his honor at the Commodore Hotel on December 9th.

"We who have served the profession since medical education and medical licensure were divorced (1892), can safely aver that no man, in or out of the profession, has ever done more for medicine and for the public in its relation to the Doctor than Dr. Downing, and in honoring him we are but paying a merited award. We represent all of the administrations of the New York State Education Department as far as its association with the control of the practice of medicine is concerned, and throughout all of these years Dr. Downing has held our esteem as he has finally won our veneration.

"We hope that the demand for seats on the night of December 9th will be such that every nook and corner will contain the admiring face of one of our colleagues as the guest of the night is called upon to acknowledge the expressions of admiration for him and for his achievements."

MAURICE J. LEWIS,
OTTO VON HOFFMAN,
WM. J. DENNO,
WM. D. CUTTER,
HAROLD RYPINS

The dinner is open to all physicians and their wives. Tickets are \$7.50 each and may be obtained from Dr. James Pedersen, 40 East 41st Street, New York.

THE WORK OF A PUBLIC HEALTH NURSE

Those who think that a public health nurse has an easy time should read the following report of an experience which is by no means unusual in a rural district.

"I was requested by a health officer to get typhoid cultures of a certain family. It seems one member of the family who is married and lives elsewhere had been at this old homestead before contracting typhoid fever, and he had been released from the hospital without the usual release culture being taken. The state department had requested that cultures from all persons involved in this family, be taken. The Health Officer was under the impression that the family I was to visit consisted of two men, around 40 and 45 years of age, and an old mother, somewhere around 90 years of age. He assured me that the road was a very difficult one to travel, but this at the time did not seem an insurmountable obstacle. The road was a mountain one, fourteen miles inland. I believe that very few, if any, cars have ever been over it. My tires were too

large for the small rut, and I skidded out of track into stone wall. However, I got out of this all right and kept on going. It was impossible to turn around anyway. The health officer had drawn me a diagram, which I was to follow. I was supposed to leave my car at a certain point not far from the house and walk up to it. I intended to do this, but a dog up at the house, having heard my car, came tearing wildly down. I forgot to mention that I nearly skidded off a log bridge just before this, but having righted myself, I discovered just in time to avoid running into it, a piece of barbed wire stretched across the road to form a gate. I managed to unhook this and got on to where I was to leave my car. I did not dare get out of the car, the dog seemed so ferocious, but while I was debating what to do, one of the men came down from the house. I walked back up with him. There was just he and his brother there. The brother without a doubt, has T.B. and is also a mental case. I have been since told that he was formerly

LEWIS COUNTY MEDICAL SOCIETY

The fall meeting of the Lewis County Medical Society was held on October 19th at the Court House in Lowville. Dr Ringrose, the President, was unable to be present and Dr Paul H von Zierolshofen was asked to preside.

Dr D G Gregor, of Watertown, read a paper on "Toxemias of Pregnancy."

Dr Fisher, President of the State Medical Society, delivered an address, outlining the activities of the State Society and the opportunity the County Societies have of assisting in the promotion of State Society programs. He dwelt particularly on the advancement of the anti-diphtheria campaign.

Dr Lawrence, the Executive Officer of the State Society, talked on the opportunities of the County Society.

Dr Stanley W Sayer, District State Health Officer, offered the County Society the assistance of the State Department of Health in promoting a program for the conduct of Well-Baby Clinics, and suggested that the County Society urge the board of supervisors to fill the position of public health nurse.

A dinner followed the meeting, to which the physicians had invited the dentists of Lowville as their guests.

SCHOHARIE COUNTY MEDICAL SOCIETY

At the meeting of the Schoharie County Medical Society held in the Cobleskill High School Library, Tuesday, October 19, 1926, the following officers were elected for 1927:

President	Meleatus Bruce,
Vice President	Leland O White,
Treasurer	Le Roy Becker,
Secretary	Herbert L Odell,
Censor	Willard T Rivenburgh,

The following committees were appointed:

Legislative Committee—Henry R Bentley, Chairman, L R Becker, C L Olendorf and H J Wright

Public Health Committee—H L Odell, W S Pomeroy and Lyman Driesbach

Publicity Committee—C L Olendorf, Chairman, H R Bentley and J J Beard

On motion it was decided to reimburse the Delegate for his traveling expenses to and from the meeting of the State Medical Society and to allow him ten dollars additional toward his other expenses, in return for which he is expected to give our county society at its next meeting a brief summary of the proceeding of the State Society's meeting. LeRoy Becker

was elected Delegate with power of substitution.

The treasurer reported sixteen members in good standing and a balance of nearly one hundred dollars on hand.

The Society was duly organized for medical relief in disaster, with its president as chairman.

The following were appointed a committee to revise the by-laws and to report at our semi-annual meeting: C L Olendorf, Chairman, D W Beard and L R Becker.

It was moved, seconded and carried that Schoharie County Medical Society fully endorse the anti-diphtheria campaign, and to further it in every way possible.

After a luncheon at Hotel Augustin, the following program was given:

"The Private Practice of Preventive Medicine," Paul B Brooks, M D, Deputy Commissioner, State Department of Health, Albany.

"Results Following Gall Bladder Operations," E MacD Stanton, M D Schenectady.

"Child Welfare," by Dr Gilmartin.

The papers were all of great interest and most helpful and each was ably discussed.

HERBERT L ODELL, Secretary

ALLEGANY COUNTY—A CORRECTION

The address of Dr John A Conway, of Hornell, District Health Officer, before the Allegany County Medical Society, was reported on page 956 of the November 15 issue of this Journal.

Dr Conway writes to correct a misstatement. He says that his subject was "Does the cat flea convey *pohomyeltis*?" The article had read louse instead of flea.

Addresses: 1 'The History and Significance of the State Society Group Insurance Plan,' H. F. Wauwig, Esq. 2 'Some Phases of Mal-Practice Suits,' Robert Oliver, Esq. 3 'The Physi-

cian's Income Versus His Saving, An Economic Paradox' Harold Hays, M.D.

General discussion and questions followed the addresses. The discussion was closed by Messrs Wauwig and Oliver and Dr. Hays.

COLUMBIA COUNTY MEDICAL SOCIETY

The Columbia County Medical Society held its annual meeting on Tuesday, October 5th at the Worth House Hudson. During the business meeting, the following officers were elected:

President—J. W. Mambert, Hudson

Vice-Pres.—Burke Diefendorf, Copake.

Secretary—Chas. R. Skinner, Hudson

The Society considered the advisability of making an appeal to the Board of Supervisors for an appropriation for a county public laboratory. After considerable discussion, a committee was appointed to investigate the matter and report at a special meeting.

A committee composed of Dr. F. C. Maxon,

Dr. C. G. Rossmun and Dr. C. R. Skinner, drew up and presented to the meeting a resolution on the death of Dr. I. C. Washburn, of Chatham, in which the sympathy of the Society was extended to the late doctor's family with their appreciation of his merits as a physician and a man.

The retiring President, Dr. H. J. Moerling, of Valatie, delivered an address and during the scientific program papers were read by Dr. L. Van Hoesen on 'Gas Bacillus Infection' and by Dr. Edgar A. Vander Veer, of Albany, on 'The Use of Insulin in Surgical Conditions.'

ROCKLAND COUNTY MEDICAL SOCIETY

The September meeting of the Rockland County Medical Society was held at the New York State Orthopedic Hospital for Children at West Haverstraw. A larger attendance than usual was registered at the meeting. Dr. John J. Nutt, surgeon in charge of the hospital with his assistants, Dr. Urquhart and Dr. McLemore, read papers and demonstrated their ideas very clearly. On account of their work being

specialized, they answered many questions propounded by their visitors. The most serious part of their work was followed by a delightful entertainment given by the children of the hospital, and the day's program was closed by a delicious luncheon. Dr. Royal Sengstacken, President of the Society, presided at the meeting.

MONROE COUNTY MEDICAL SOCIETY

The regular meeting of the Monroe County Medical Society was held on October 19, 1926, with the President, Dr. A. G. Morris presiding.

Dr. S. J. Applebaum gave an address as a memorial to the late Dr. S. H. Rosenthal recalling his pleasing personality, his public spirit and his patriotic service in the World War.

Following discussion of the certified milk situation and the Milk Commission, on motion of the Society, the President appointed a special committee to study the question reporting at the annual meeting in December. The committee consists of Drs. A. S. Miller, chairman, S. J. Applebaum, S. Bayne-Jones, A. D. Kaiser and J. W. McGill.

On recommendation of the Committee by motion of the Society, the state-wide anti-diphtheria campaign was formally endorsed and the President was authorized to appoint an official

representative of the Society to act in conjunction with other organizations, medical and lay. Dr. Morris appointed Dr. C. G. Lenhart, Spencerport, N. Y., as this representative.

The scientific program consisted of a paper by Dr. B. T. Simpson, Director, State Institute for Study of Malignant Disease, Buffalo, N. Y., who gave a very interesting and illuminating résumé of the work done on the Cancer Problem, with special emphasis on an evaluation of the more recent experimental work along this line. Dr. Simpson stated his belief that there is no parasitic or specific bacterial cause of malignant disease but that the causative factors are chronic injury and hereditary tendency or lack of resistance of the tissue cells to injury. Dr. Simpson gave some very practical suggestions as to prophylaxis, education of the laity and treatment (page 979).

LEWIS COUNTY MEDICAL SOCIETY

The fall meeting of the Lewis County Medical Society was held on October 19th at the Court House in Lowville. Dr Ringrose, the President, was unable to be present and Dr Paul H von Zierolshoten was asked to preside.

Dr D G Gregor, of Watertown, read a paper on "Toxemias of Pregnancy."

Dr Fisher, President of the State Medical Society, delivered an address, outlining the activities of the State Society and the opportunity the County Societies have of assisting in the promotion of State Society programs. He dwelt particularly on the advancement of the anti-diphtheria campaign.

Dr Lawrence, the Executive Officer of the State Society, talked on the opportunities of the County Society.

Dr Stanley W Sayer, District State Health Officer, offered the County Society the assistance of the State Department of Health in promoting a program for the conduct of Well-Baby Clinics, and suggested that the County Society urge the board of supervisors to fill the position of public health nurse.

A dinner followed the meeting, to which the physicians had invited the dentists of Lowville as their guests.

SCHOHARIE COUNTY MEDICAL SOCIETY

ALLEGANY COUNTY—A CORRECTION

The address of Dr John A Conway, of Hornell, District Health Officer, before the Allegany County Medical Society, was reported on page 956 of the November 15 issue of this Journal.

Dr Conway writes to correct a misstatement. He says that his subject was "Does the cat flea convey pihomyelitis?" The article had read louse instead of flea.

THE DAILY PRESS

TARDINESS OF PHYSICIANS

Are physicians habitually late in keeping their appointments? They are, according to the following editorial in the *New York Sun* on November 11th

"Unpunctuality has come to be one of the physician's undisputed privileges. He is just as cordially welcomed when he appears half an hour late as if he had been on time. He is quite unashamed. Patients may be nervous, watchers solicitous, but a shower of grateful smiles washes away the suspense when the doctor's presence is assured. He knows he will never be blamed for being tardy. He has earned the right.

"But how? The world expects all the rest of its practitioners to be on time. Nobody overlooks half an hour's delinquency in them. Who would tolerate a lawyer habitually late at his appointments? A sharp word would bring a dilatory functionary of that profession up with a short stop. All the world is, however, indulgent to the physician.

"Some of his delays are excusable. Patients may require more time than was expected. They may not be at once accessible. One delay extends right along the line, so that day the doctor is

more certain than usual to be late after the initial pause. Yet he has not always such an excuse.

"Patients have learned what a movable feast office hours are. They esteem themselves fortunate if they get in and out of the office with comparatively little delay. If they are solvent, conscientious patients it rarely happens that the doctor speeds them on their way.

"When making his round of professional calls the doctor does not even hurry himself. He may linger to tell the patient another joke or to chat with the family. His bedside manner, whatever it happens to be, must be maintained. Unpunctuality is a part of the professional deportment of so many doctors that they would not part with it at any price. It may be that patients have come to look upon his tardiness as one of the evidences of a physician's capacity and would not have him prompt. The present danger of such a startling innovation seems slight. The doctor has no idea of being on time."

This editorial is evidently intended to be taken seriously, and is probably based on some unpleasant experience of the newspaper writer. However, it is of value to doctors for it reveals their status in the eyes of at least a part of the public.

WHAT INSANITY IS AND IS NOT

The newspapers have given wide publicity to a pamphlet issued by the National Committee on Mental Hygiene, 370 Seventh Avenue, New York City, stating the popular misconceptions of insanity as contrasted with the ideas of modern psychiatrists.

The following eleven misconceptions are listed, and after each one the modern attitude of the medical profession is given.

1—"That insanity comes suddenly."

"Insanity develops gradually over shorter or longer periods of time."

2—"That once insane always insane."

"Many of the insane are restored to health after a period of hospital treatment."

3—"That insanity is a disgrace."

"Insanity is a condition no more to be ashamed of than pneumonia or a broken limb."

4—"That insanity is an unfortunate visitation to be regarded with resignation and fatalism."

"Insanity is a mental disease and should receive medical attention, just as tuberculosis, cancer or other physical conditions."

5—"That mental disease is incurable."

"Many persons with mental disease are being cured today and restored to health and normality."

6—"That asylums for the insane are dreadful places and that admission to them rings down the curtain on the lives of the victims."

"Our asylums are being turned into hospitals in which the insane receive medical care and treatment, and from which between 25 and 40 per cent are discharged recovered or improved."

7—"That emotional shock, the loss of dear ones, disappointment in love, economic loss, and other human misfortunes cause insanity."

"Personal misfortunes and tragedies are frequently the precipitating causes of insanity, but that the accumulation of a variety of factors inherent in the progressive

life experience of the individual is really responsible for upsetting mental balance and bringing on mental breakdowns"

8—"That insanity is a specific disease entity"

"Insanity is a convenient term used by the courts to denote irresponsibility in the eyes of the law, and that there are many different kinds of mental disorder just as there are many kinds of physical disorder"

9—"That nobody can guard against mental disease"

"There are usually danger signals and symptoms of an approaching breakdown

that can be recognized and medically dealt with"

10—"That a person is either sane or insane."

"There are different degrees of mental health, just as there are varying degrees of physical health"

11—"That 'nervous breakdown' is a disease of the nerves"

"Nervous breakdown is in reality a mental condition in which there is seldom anything organically wrong with the nervous system"

Physicians will find this list of value in treating psycho-neurotic patients

RABIES

A denial of the existence of rabies in dogs and human beings sometimes appears in the newspapers and magazines, though less often than in former years. The *New York Herald Tribune* of November 22 prints a letter which is typical and follows the old argument that the writer has never seen a mad dog and therefore there is no such animal.

The writer also argues against the preventive vaccination of dogs, and says that ordinances requiring it are passed at the instigation of veterinarians who get five dollars per dog and make more money by that work than by all their other practice. He then discusses the passing of personal liberty and says "soon we shall be unable even to afford safe shelter to man's only friend, the dog"

Balanced against this article is one entitled "A case of Human Rabies" printed in the *Weekly Bulletin* of the Department of Health of the City of New York of November 13th. This was the first case of human rabies in New York City, in more than three years.

The article refers to the attempt of the Department of Health to educate the people regarding rabies and says

"Since early in January and thereafter, from time to time, the Department of Health has issued warnings on the prevalence of dog rabies in New York City. Repeatedly the attention of the medical profession and the public at large has been called to the menace of this situation. Warnings have been issued to all dog owners to muzzle their animals and to keep them on a leash. Instructions on the care of animals suspected of rabies were published through our official communications and through the press. And the importance of treating those bitten by rabid or sus-

pected animals with anti-rabic vaccine has been repeatedly emphasized"

The article refers to the prevalence of rabies and to the increase in the number of dog bites in New York City and vicinity. The City of White Plains has declared a quarantine against dogs and has spent a special appropriation of \$3,000 in anti-rabic work and is asking for more money. Dogs have been proved rabid in Nassau County. Fortunately, most persons who are bitten go to a physician at once, and the doctors almost always give them preventive inoculation. However, now and then the inoculations are refused, as they were in the case reported by the Department of Health.

The case was a boy aged ten, who was attacked by a stray chow dog on August 14th and was bitten on the arm, face and thigh. The preventive inoculations were refused, and on August 21 symptoms of rabies appeared. Death occurred on the seventh day. The dog which did the biting wore a license number and its owner made the usual excuse that the dog had always been well and kindly and had always been muzzled when it was in the street! The article concludes

"This case of human rabies brings to the fore again the urgent necessity of enforcing the laws on dogs. It impresses us with the necessity and wisdom of widespread, universal anti-rabies vaccination of dogs, the advisability of requiring evidence of such vaccination as a condition for licensing, the destruction of all dogs, vaccinated or unvaccinated, that show a vicious character, and the ridding of the streets of all stray dogs. The Commissioner has called a conference of interested individuals to consider the scientific and practical aspects of the anti-rabic vaccination of dogs. We expect to report on this conference in the near future."

BOOKS RECEIVED

Acknowledgment of all books received will be made in this column and this will be deemed by us a full equivalent to those sending them. A selection from this column will be made for review, as dictated by their merits, or in the interests of our readers.

- SURGICAL CLINICS OF NORTH AMERICA** Volume 6 No 4 August, 1926 (Chicago Number) Published every other month by the W B Saunders Company, Philadelphia and London. Per Clinic Year (6 issues) Cloth, \$16 00 net, paper, \$12 00 net.

BOOK REVIEWS

ELECTROTHERMIC METHODS IN THE TREATMENT OF NEOPLASTIC DISEASES Designed as a Practical Handbook of Surgical Electrotherapy for the Use of Practitioners and Students By J DOUGLAS MORGAN, B.A., M.D. 12mo of 172 pages, with illustrations Philadelphia, F. A. Davis Company, 1926 Cloth, \$2.50

A concise monograph in which the various methods of electrothermic therapy are clearly outlined and explained. This comparatively new type of surgery is in its infancy and in many ways appeals to reasoning as preferable to the older surgery which seems to be striking a balance and its virtues more properly evaluated.

The author does not claim electrocoagulation or desiccations is a cure-all but successively discusses the diseases for which it is preeminently adapted. The heretofore rather confusing terms applied to this type of treatment are well explained so that no longer is "radio-knife" to be confused with endothermy or desiccation.

No claim to originality is made but its object is well attained, namely—"a short account of the means by which desiccation and coagulation are produced and the manner of their application."

The author recommends in many cases supplemental treatment with X-Ray and radium especially when deep malignancy and metastases are present. The subject is well and honestly presented and appears to be the first book published dealing exclusively with electrothermic methods

MILTON G WASCH

CARBOHYDRATE METABOLISM AND INSULIN By JOHN JAMES RICKARD MACLEOD F.R.S., M.B. Octavo of 357 pages with illustrations London and New York, Longmans, Green and Company, 1926 Cloth, \$6.00 (Monographs on Physiology)

There has been no book previously written on this subject which so adequately covers the field. The introductory part of the book reviews the steps incident to the discovery of insulin in such a form as to be clinically usable in a safe way. To each investigator credit is given for what the author feels he really did. This part is truly pleasing, as the counter claims that appeared some time back are so presented with references that anyone who cares to study the matter has the way made easy. After reading this part of the book, one is impressed with the fact that an entity made popular is often not new, even the name for it.

Anyone treating diabetes mellitus should have at his command data which will enable him to have a comprehensive knowledge of the physiology of the insular tissue of the pancreas. The data are well presented in this book. Although it is well established what can be accomplished by the use of insulin, the method of the accomplishment is not settled. The author points out the ability of the normal insular tissue to respond to whatever carbohydrate load is placed on it.

Not only is the book an excellent aid to the physician caring for the sick, but it is a manual for investigators in the problems of diabetes mellitus as the fields needing most study are clearly surveyed.

J ARTHUR BUCHANAN

LOCAL ANESTHESIA IN OTOLARYNGOLOGY AND RHINOLOGY By JAMES JOSEPH KING, A.B., M.D. Octavo of 205 pages, with 21 illustrations New York, Paul B. Hoeber, Inc., 1926 Cloth, \$5.00

This volume deals with the subject in three different parts. Part one is devoted to local anesthesia, technique in otolaryngology and rhinology. Part two concerns itself with the reports of the committees of the American

Medical Association on the toxicity, advantages and disadvantages of the various local anesthetics in nose and throat work. Part three is a tabulation of forty-three deaths reported from the use of local anesthesia in this field. The tabulation is in the form of a packet which affords easy reading and study.

The author has described fully, cocaine, novocaine, butyn and epinephrin. The technique which the author uses and that of other operators is indicated in detail.

A chapter on the synergistic action of morphine, magnesium sulphate and novocaine in nose and throat surgery is included. This is a new phase of local anesthesia whose value remains to be proven. It has given the author excellent results in local tonsillectomy.

The committee reports, as given in part two, are interesting and instructive. These reports contain recommendations that will prove of value to all who use local anesthesia. These reports are brought up to date and are edited by Dr. Emil Mayer and prefaced by Professor Robert A. Hatcher.

The volume is to be highly recommended to all otolaryngologists

B. H. ABRAHAMSON

INTERNATIONAL CLINICS Volume 1 Thirty-Sixth Series, 1926. Octavo of 309 pages, with illustrations Philadelphia and London, J. B. Lippincott Company, 1926

The two most interesting contributions to this number are the one on Massive Collapse of the Lungs, by Gwyn, and the one on Nephrosis, by Mason. These articles are both well presented, and the one on nephrosis particularly valuable because it covers the life history of a case which was well studied, and the studies seem to upset some prevailing theories.

Under "Medical Progress" a case of so-called "Silent Diabetes." It is a very rare thing for a patient with diabetes mellitus to have a very low blood sugar, when not taking insulin, or even with that medication unless an overdose has been given. This case of silent diabetes is probably a case of something else. The information presented under the general heading of progress is in reality a good review of the literature on the subjects considered, and all medical literature certainly does not represent progress, in fact, at times progress is retarded by certain articles.

J ARTHUR BUCHANAN

PITFALLS OF SURGERY By HAROLD BURROWS, C. B. E., M. B., B. S., F. R. C. S. Second Edition William Wood and Co., New York, 1925 Price \$4.50

Much valuable information can be acquired from a careful study of the mishaps occurring in the course of one's surgical practice. Conscientious acknowledgment of our surgical failures, with deliberate notation for future reference, of the determining factors in such cases and an honest appreciation of our culpability or responsibility, is bound to insure an improvement in results.

"Pitfalls of Surgery," is a most interesting and valuable contribution to current surgical literature. The second edition, recently published, is well arranged, readable, and covers a wide field of surgery. Essentially practical and helpful, it will be a stimulus to the surgeon young or old.

The author, Mr. Burrows, a widely known teacher of surgery, experienced by virtue of years of busy surgical practice, presents the facts in his cases so logically and convincingly that the reader readily grasps the surgical principle involved and cannot do otherwise than be impressed.

T. M. B.

SOME ENCOURAGEMENTS IN CANCER SURGERY By G GREY TURNER, F.R.C.S. (Eng.), Honorary Surgeon Royal Infirmary, Newcastle-upon-Tyne. William Wood & Co, New York, 1925 Price \$3.50

In "Some Encouragements in Cancer Surgery," G Grey Turner has presented the profession with a very readable, interesting and helpful monograph. This little book of 75 pages contains the substance of a lantern demonstration before the Surgical Section of the Royal Society.

The arrangement of the material is regional and includes cases of cancer of the rectum, large bowel, stomach, breast, bladder, mouth, etc. The author's purpose is to call attention to a brighter side of cancer surgery. He relates some very remarkable recoveries, some unexpected after local operation, upon apparently extensive, adherent and infiltrating growths. The diagnosis in these cases was confirmed by microscopic examination of the growth following its removal and examination of the slide and section at the time of the follow-up examination. The illustrations of specimens and microscopic sections are complete and convincing.

Mr Turner is emphatic that the outlook for patients suffering from malignant disease is brighter than usually supposed. He insists on vigorous and thorough surgical attack as the best chance for cure providing there is no unequivocal evidence of dissemination.

The book strikes an optimistic note and coming from one who speaks with the authority commensurate with a rich and varied experience is a most valuable contribution to the literature on cancer. T M B

A COMPEND OF OBSTETRICS Especially Adapted to the Use of Medical Students and Physicians. Revised and Edited by Clifford B Lull, M.D. Tenth Edition. 16mo of 283 pages with 84 illustrations. Philadelphia, P. Blakiston's Son and Co., 1925 Cloth, \$2.00 (Blakiston's Compendis)

Brought up to date, this popular Vademecum of old and young practitioners has again made its appearance in the form of a revised edition. In this revision, a number of additions have been made, including a resumé of Potter's Version. It has many illustrations. Its brevity and up-to-dateness recommend it to those wishing to make a rapid review of the subject.

L. KOEMPEL

L'ANATOMIE EN POCHE. By VICTOR PAUCHET and S. DUPRET. 12mo. of 316 pages, with 297 plates. Paris, Gaston Doin & Cie, 1926 Paper, 25 Francs. Dr Pauchet is a French surgeon well known to

American visitors to Paris. As a teacher of anatomy and operative surgery he conceived the idea of making his notes and dissections permanent through the drawings of Dupret.

The "pocket anatomy" here reviewed is the result of this coalition and it must be said that the result is quite satisfactory. It is a text book without text, a series of 297 plates made from drawings of great clearness, well colored and explained by the connection of the tissues with the anatomical term by means of dotted lines. The word "atlas" applied by the authors to their work is self explanatory and gives the exact idea of the nature of the book, namely a combination of drawings and terms—nothing more.

WM HENRY DONNELLY

THE BACTERIOPHAGE AND ITS BEHAVIOR. By F d'HERELLE, M.D. Translated by GEORGE H SMITH, Ph.D.

Octavo of 629 pages. Baltimore, Williams and Wilkins Company, 1926. Cloth, \$8.00

Those who have not read d'Herelle's previous works will find in this latest volume a complete history of his researches on the bacteriophage. It is a fascinating story beginning with an accidental observation made in 1909 while studying an epidemic among locusts in Mexico. For a time he followed a false trail, then in August, 1916, in Paris he found that the stools of a patient convalescing from Shiga dysentery contained something which dissolved dysentery bacilli. Others had noted similar lysis of bacteria but it remained for d'Herelle, with true scientific curiosity, to seek and find the cause of this phenomenon. His researches led him to Indo-China and back again, he studied many diseases in birds, animals and man. Even amidst his duties in the Great War he found time for a prodigious amount of experimentation and for prolific writing. Dealing with a new, ultra-microscopic principle, he had to invent new bacteriological methods. One is equally impressed with his immense industry and his scientific genius. The world now admits that he is the discoverer of a new principle in immunity, a principle which dissolves bacteria and plays an important part in natural recovery from certain diseases. His work has been confirmed by many. Barbone in Indo-China has almost disappeared and Brazil is using the bacteriophage with great success in dysentery. The one point his critics will not admit is d'Herelle's claim that the bacteriophage is a living, infravisible organism parasitizing bacteria.

The introduction gives an historical resume and a complete description of the author's technic and apparatus. Part I deals with bacteriophagy in all its aspects, with the bacteria which, to date, have been found susceptible to this process. Part II is a study of the characteristics of the bacteriophage. Part III deals with the bacteriophage in various diseases and its therapeutic use by the author and others. This part will appeal especially to clinicians, though it is but fair to say that bacteriophage therapy presents many technical difficulties and much remains to be done here.

E. B. SMITH

MEDICAL DIAGNOSIS FOR THE STUDENT AND PRACTITIONER. By CHARLES LYMAN GREENE, M.D. Sixth edition revised and enlarged. Octavo of 1468 pages with 14 colored plates and 709 other illustrations. Philadelphia, P. Blakiston's Son and Company, 1926 Cloth, \$12.00

The sixth edition of this well-known book is not the type one is apt to read from cover to cover in orderly sequence, but rather according to one's immediate requirements or mood. In the first case, a wealth of valuable information on the laboratory, clinical and diagnostic aspect of medicine is available, and if the latter should be the case there is always an instructive and interesting presentation of the subject. The author's clinical experience and ability as a teacher of medicine, gives the book that something which we will term medical personality and which differentiates it from a mere collection of hard, dry facts.

Medical diseases are presented to impress the distinguishing and diagnostic features and only those laboratory procedures of time-proven usefulness. Physical diagnosis, particularly that devoted to the examination of the chest, is very well described. The illustrations throughout are in keeping with the high standard of the text and rarely does one come across a book of this character where both are so well maintained in the various sections. The arrangement and typography helps to emphasize that which is important. A very complete index will be found useful. This is a book well worth having. H. W.

RHINOLOGICAL FINDINGS AND TREATMENT OF CASES OF RETROBULBAR OPTIC NEURITIS*

By MARK J GOTTLIEB, M D, NEW YORK

From the Otolaryngological Service of Beth Israel Hospital.

THE rhinoscopic findings in cases of retrobulbar optic neuritis are practically negligible as far as their value in establishing an etiological relationship between the paranasal sinuses and the involvement of the optic nerve

In recent years this important subject has attracted the attention of many capable investigators and an extensive literature has been accumulated and yet no definite criteria have been established by which on examining the interior of the nose a statement may be made that the sinuses do or do not cause the existing diminution in vision. White of Boston, who has studied this subject from all angles, believes that there must be some fundamental difference from that which is usually found in the anatomical relation of the posterior portion of the middle turbinate to the septum, which more or less crowds this part of the nasal chamber. An acute non-purulent infection superadded would produce swelling and edema sufficient to compress all other tissues in this region and affect the optic nerve either by direct extension or collateral edema. He comes to this conclusion because he has found in a large percentage of cases of retrobulbar optic neuritis that the septum was deviated and crowded an already enlarged posterior portion of the middle turbinate and that at times the turbinate was found to have a large cell in its body.

This conclusion might easily explain cases of unilateral retrobulbar optic neuritis because the septum could only be deviated to one side at a place where it would be opposite the posterior end of the middle turbinate. It does not, however, account for the bilateral cases wherein the involvement of one side is nearly as extensive as that of the other. We have observed cases of bilateral involvement of the optic nerves in patients whose nasal chambers were unusually roomy and the turbinates were not in contact with the septum. A suggestive observation is that cases of this dis-

ease occur in groups. Three or four have come to the writer within two months or so and then, except for sporadic cases, another series would appear a year or so after. Is it not likely that retrobulbar optic neuritis from paranasal sinus disease of the non-suppurative type is due to some form of bacterial infection which is as yet not understood?

It is generally agreed that acute or chronic purulent ethmoiditis and sphenoiditis is not a necessary finding in cases of retrobulbar optic neuritis. Cases of this kind, however, do occur in which suppurating sinuses cause this malady. The finding of purulent discharge in the nose in a case of diminution of the visual acuity may be suggestive of a very likely etiological factor. However, the great majority of cases of retrobulbar optic neuritis are not associated with purulent inflammation of the sinuses. It is rather the absence of discharge and other evidences of inflammatory reaction which characterizes this disease.

The middle turbinate may look perfectly normal. On the other hand, the author has observed in some cases of retrobulbar optic neuritis of nasal origin that the middle turbinate looked dry, that its surface was dotted with very small red elevations between which the mucus membrane looked pale and glossy. Whether this observation has any significance cannot be stated. Occasionally denuded bone in the sphenoid may be felt with the probe. More often, however, the sphenoid walls feel as smooth as those not associated with the retrobulbar optic neuritis.

The histological findings in the scrapings from the sinuses and turbinate bones are vague and similar processes may be encountered in heads wherein the optic nerves are not the seat of a neuritis. The microscopical appearance of the tissues in the nose varies with the age of the patient, the state of his general health, the season of the year, the intensity of the climate. These variations may border on disease and be construed

diminish This necessitates further unnecessary operative intervention

Miss M B, age 17 years, school girl Appeared first for examination and treatment on February 11, 1924, complaining of frontal headache, tenderness over both frontal sinuses, and nasal discharge The pain in the forehead continued after the nasal discharge had ceased, and the patient did not complain of difficulty with her eyes, but because of the fact that the headache persisted in spite of treatment, she was sent to Dr Cyril Barnert for the purpose of a routine examination of her eyes Surprising as it may seem, the report of the eye findings indicated that the patient was rapidly losing her sight X-ray showed no disease of the nasal accessory sinuses The Wassermann was negative All other causes having been eliminated, on June 13, 1924, a bilateral ethmosphenoidectomy was performed and both middle turbinates were preserved Following the operation, the headaches disappeared On July 29, the ophthalmologist reported a moderate improvement in the seeing capacity, with a broadening of the fields for form and color Directly after that, however, her vision again began to be poor and the question arose as to what procedure should be followed to prevent her vision from becoming permanently impaired It was then decided to again attack both ethmoid areas, cut away all scar tissue, and remove both middle turbinates This produced an immediate and progressive improvement so much so, that on August 29, her vision

show small sections of tissue typical of nasal mucosa, each containing a small area of cancellous bone The glands are abundant and show no evidence of increased activity The blood vessels show no thickening and are surrounded by a well developed erectile envelope of smooth muscle The bone is normal and the contained marrow is fatty The mucosa is absent in many areas, but this is an artifact Such as is preserved shows no infil-

FIG 4 Fibrous Tissue, Left Ethmoid Case Miss I B

FIG 3 Fibrous Tissue, Left Ethmoid, Case Miss I B

was found to be practically normal and has remained so to date The specimens from both ethmoids and sphenoids were subdivided to Dr Eli Moschkowitz, who has been kind enough to render the following report Both right and left ethmoids show the same structure The slides

tration or desquamation The stroma is fairly firm and is more fibrous than the average ethmoid There are a few areas of round celled infiltration, but they are sparse and not more abundant than the vast majority of ethmoids show There are no eosinophiles

I have seen nine cases of retrobulbar optic neuritis Eight of these were bilateral and one unilateral When the affection is on both sides, both ethmoids and sphenoids should be broken down The procedure can be done at one sitting I have never seen ill effects from it This practice is contrary to that of some excellent rhinologists The unilateral case which was observed by the writer, was one wherein at some time previous a piece of cotton, accidentally left by another doctor, was jammed between the middle turbinate and the septum On the day scheduled for operation the patient sneezed out the cotton and the optic neuritis promptly cleared up

Usually within eight or twelve hours after the operation, the patient will tell you that the vision has improved and continues to improve. In a certain few, the vision continues to diminish after the operation and then suddenly veers around and the recovery is uneventful, but prolonged

This is very well illustrated in the case of Miss I B—Referred by Dr Cyril Barnert with the following note "I am referring Miss I B who

as pathological by one who does not correlate the clinical with the laboratorial. Even in patients in whom the surgeon has found frank pus coming from the ethmoid region, sections of such ethmoids reveal slight deviations from the normal. Never does one find, as would be expected, pockets of pus, polynuclear infiltrations, mucosal ulcerations, or indeed any changes usually associated with chronic purulent mucosal inflammations. In

retrobulbar optic neuritis, 29 of which recovered without operative intervention, the five remaining cases apparently, according to the report, either became worse or their condition remained stationary. Lenoir and Beaujeu report 16 cases, seven recovered spontaneously, 4 retained 9/10 of their vision, 3 retained 8/10 and 2 retained 1/10. Chaillous reports 4 cases that recovered without operation. These were treated with injections of cyanide of mercury.

The rational procedure for the handling of a case of retrobulbar optic neuritis palliatively, would be to give the patient a brisk cathartic, shrink up the turbinates with adrenalin and cocaine, followed by suction. This may be supplemented by tampons containing some of the silver albuminate salt. The giving of a series of injections of autogenous vaccines may be undertaken. This management should be given in conjunction with an ophthalmologist who must see the patient daily so as to determine the condition of the optic nerves and serve as a safeguard against continuing this treatment when the patient is getting rapidly worse. In such an event prompt surgical measures should be applied.

The surgical treatment consists of a thorough removal of all possible ethmoid tissues and breaking down the anterior wall of the sphenoid cavity. The middle turbinate should be removed for it has been the author's experience that the outer surface of the turbinate will in a certain number of cases adhere to the orbital plate of the ethmoid.

FIG. 1 Left Ethmoid, Case Miss M. B.

most of the cases of retrobulbar optic neuritis a functionless overgrowth of supporting tissue is found, but such hyperplasia is encountered in a great many sinuses which are not associated with this disease. It is possible, as White has suggested, that the hyperplasia predisposes and an infection excites an edema which compresses the nerve in its unyielding canal.

The management of cases of retrobulbar optic neuritis may be divided into expectant and operative treatment. Unless haste is essential, the patient should have a blood Wassermann examination, radiograph of the nasal accessory sinuses and of the optic canals. The teeth should be thoroughly examined by the dentist. If the optic canals are large there is no necessity for hurry and the patient may recover without surgical intervention. White believes that the disease, in cases where the canals are large, is not due to direct extension, but from absorption of toxins or bacteria from diseased foci, such as chronic purulent disease of one or more of the nasal accessory sinuses, diseased tonsils or teeth.

Palliative treatment has not been practised in this country because of the fear that the patient would go blind and a valuable opportunity for curing the patient, lost forever.

In Europe, however, expectant treatment has been undertaken and Weill reports 34 cases of

FIG. 2 Fibrous Tissue, Left Ethmoid, Case Miss M. B.

and reproduce the same conditions which obtained before the operation. In such an event, as will be shown in the following case history, the sight will become normal directly after the ethmoidectomy and sphenoidectomy and within a reasonably short time thereafter the visual acuity again gradually

to the external wall of the nose. Under local treatment to the nose and autogenous vaccine therapy, his vision improved and remained so up to January 31, 1925, when he was last examined.

The after care of cases of retrobulbar optic neuritis that have been operated upon is the same as that which would be needed in any case wherein the sphenoid and ethmoid sinuses have been attacked surgically. It is my practice to begin to treat the operated field with the tampons as suggested by Dowling, beginning about forty-eight hours after the operation and continuing this pro-

cedure over a long period of time, at first twice daily, and then daily, until the case is healed. During the after care, the ophthalmologist should occasionally examine the patient's eyes to determine the extent and rapidity of the improvement, if any.

ROENTGEN FINDINGS OF OPTIC CANALS IN BLINDNESS DUE TO NASAL ACCESSORY SINUS DISEASE*

By HENRY K. TAYLOR, M.D., NEW YORK CITY

From the Department of Roentgenology and Otolaryngology, Beth Israel Hospital, New York City

THE optic canal is an osseous structure, affording protection to the optic nerve and ophthalmic artery which accompanies it. Should the nerve itself, or its enveloping sheath become swollen, in a contracted canal the pressure of the edema against the unyielding wall will be sufficient to produce an optic atrophy. When the canal is large or that of the average normal this may not necessarily occur.

mm along the inferior root and about 10 mm along the superior root, the latter measurement varying, depending upon development. The diameter of the canal is about 5 mm. The average diameter of the canal, according to Whitnall is 5 to 6 mm. Wilbrand and Saenger give the average as 7 mm. White gives the the average as 5.17 mm. According to Goalwin, the average is between 4 and 5 mm. Piersol gives the diameter of the optic nerve

FIG. 1 Normal circular optic canal, 4.8 x 5.6 mm.

FIG. 2 Normal triangular optic canal, 4.0 x 5.2 mm.

Piersol gives the anatomy of the canal as follows. The lesser wings of the sphenoid arise by two roots. The superior root is a plate covering the presphenoid, which forms the posterior part of the anterior fossa of the base of the skull and the roof of the orbit. The inferior root is a strong process arising from the side of the body of the sphenoid. These two roots and the body of the sphenoid enclose a canal, the optic canal. The canal measures 5

as 3 to 4 mm. From this it is evident that a moderate swelling could cause sufficient pressure to cause a rapid degeneration.

Occasionally, due to faulty development, the optic nerve may be devoid of its osseous protection, as shown by Onodi, and pass through an ethmoid cell or through the sphenoidal sinus.

According to Van Gilse, there is a remnant of the craniopharyngeous lateralis canal, which appears as an aperture in the wall of the sphenoid cavity. This leads with a con-

* Read at the Annual Meeting of the Medical Society of the State of New York at New York, March 31, 1926.

came to me this morning with a history of rapidly failing vision in the right eye for the last ten days. Examination showed normal conjunctivae, musculature, pupils, media and fundi in both eyes. There is a slight tenderness on backward pressure over the right globe. Perimetry disclosed a marked concentric contraction for form in the right eye with an entire absence of color perception. The left eye has a normal field for form and a contracted field for color with a relative central color scotoma. The vision in the right eye is reduced to counting fingers at six feet and can be improved but slightly with correction, although the girl stated that in an examination made while in Atlantic City a few weeks ago, the vision in the right eye was 20/20. The vision in the left eye is normal with correction of the hyperopic error.

We are undoubtedly dealing with an acute retrobulbar optic neuritis in the right eye and a similar incipient condition in the left, and in view of the very rapid loss of vision, I would recommend an immediate exploration of the right ethmoid (and of the left as well, if practicable), even if there is no clinical or X-ray evidence of sinus disease." Signed C B, M D

X-ray pictures were immediately made and a negative report was obtained. There was a deviation of the septum in its posterior portion, the convexity of the bend being toward the right. However, this deviation did not crowd this area and it did not interfere with the operative procedure. It was impossible to probe the sphenoid sinuses.

On the following day both ethmoids were opened and all tissue removed with meticulous care. The right sphenoid was found absent and the left was very shallow, but extended deeply down into the pterygoid plate.

The patient did not improve as was expected and although the left eye became somewhat better, the right became progressively worse. This gave us a great deal of anxiety and we proceeded to eliminate causes. The Wassermann was found to be negative. The dentist found two teeth that were apparently diseased and removed them. The right eye continued to get worse, so much so that finally she could only distinguish light, and then she suddenly improved and has continued to do so ever since.

Pathological report by Dr. Eli Moschkowitz. Both right and left ethmoids show the same structure. The slides show one or two large and several small pieces of nasal mucosa, some containing small areas of cancellous bone. The structure is practically identical with that found in the case of M B, except that the stroma is perhaps more fibrous and there is no infiltration with round cells. The mucosa is everywhere well preserved.

In cases wherein a chronic purulent sinusitis exists as the etiologic factor the vision does not

improve as rapidly as in the non-suppurative variety because the retrobulbar optic neuritis is probably of the chronic type also. Another factor which interferes with prompt recovery in such cases is that there may be a combination of compression on the nerve and toxic absorption from the purulent focus. In the event that the condition does not continue to improve in such a case, it has been found valuable to use suction, douching, tamponage and autogenous vaccines. This will be illustrated very well in the following case history.

Mr. J S L, age 60 years, bank examiner. Appeared first for examination on March 6, 1924. For a great many years he has had a thick purulent discharge from the nose, necessitating the use of many handkerchiefs during the day, also expectorates constantly mucopurulent material which drops from the back of his nose. Catches cold frequently. For the past seven months has experienced difficulty in concentrating his vision, principally with the right eye. When addressing the golf ball, is compelled to focus his vision repeatedly. He also complains of a mild photophobia. Mucopurulent material is seen dripping from the middle meatus on both sides, but more from the right. The right frontal sinus is cloudy, the left clear to transillumination. The right frontal sinus and antrum of Highmore are tender. He was referred to Dr. Cyril Barnert for eye examination, with the following results:

"He has a definite hyperopic astigmatism and presbyopia for which his present glasses are quite adequate. Perimetry discloses the fact that his fields are very good for form, while his color fields are relatively constricted, the right more than the left. This, however, together with his statement that he is at times conscious of a central blur makes a diagnosis of a beginning of a retrobulbar neuritis very probable. I think his sinuses should be looked into."

Accordingly, on March 15, 1924, a bilateral ethmosphenoidectomy was done under cocaine anesthesia. The right middle turbinate was preserved. The left was sacrificed because it interfered with the approach to the sphenoid sinuses. The sphenoid sinuses were found to be located unusually low down and in both instances extended deeply into the pterygoid plate. The right sphenoid was found to be distinctly diseased. Three days after the operation, the patient experienced a very decided improvement in his vision. This improvement continued for a few months, when difficulties of seeing began again to be manifest. On October 7, 1924, he was again examined by Dr. Barnert, who found an increased constriction of the fields, especially for form. On examination of the nose it was found that there was an increase of the purulent discharge, and that the middle turbinate on the right side which was not removed at the time of the operation hung freely in the nasal chamber and was not adherent.

regular foramen is usually due to variations in development of the skull

Adjacent disease, particularly of the posterior ethmoids and sphenoids, is not always demonstrable. However it is known that sinus disease may exist without clinical or roent-

Fig 5 Irregular optic canal 3.2 x 5.6 mm, ocephaly, double optic atrophy since childhood. Sinuses negative.

genographic evidence. If there are eye symptoms or optic nerve involvement associated with an optic canal that measures less than 4 mm in diameter, and no cause found for the existing condition, operative intervention of the sinuses is advisable. This procedure, however, is not necessarily indicated when the canal measures over 5 mm in diameter. In cases with optic nerve involvement, the majority of the canals are oval, triangular or irregular. In some instances circular canals are found. Some of these canals are approximately of the average diameter, the majority of them, however, measure less than 5 mm in diameter.

Fig 6. Circular optic canal R. 4.3 x 4.0 L. 5.2 x 4.4 mm, sudden blindness, right eye. Sinuses showed a slight change in illumination of the ethmoids. Gradual improvement beginning two days after operation. Operative findings, no pus, hyperplastic condition of ethmoids and sphenoids.

Loss of vision may at times be accounted for by extrinsic causes which result in an irregular contraction of the optic foramen, this in turn results in pressure upon the optic nerve. Virchow and Manz have demonstrated that the cause of blindness in a number of instances, was due to arrested development of the skull in earliest youth, premature ossification of the skull, and to hyperostosis.

The roentgenographic appearance of the optic canal has a definite but limited value. The clinical findings of ocular disease are definite. The exact cause, however, may not be known. The roentgen findings establish only the urgency necessary for operative interference to avert irreparable damage to the optic nerve. A contracted canal warrants early interference. A canal of normal size, does not necessarily require early interference. A normal canal permits of further study to determine the exact cause, which at times, may not be due to sinus disease.

OPHTHALMIC FINDINGS IN NASAL ACCESSORY SINUS DISEASES*

By CYRIL BARNERT, M.D., NEW YORK CITY

THAT the eye may be involved in disease of the neighboring nasal cavities is a well established fact, but the true significance and importance of these eye findings as a diagnostic aid is perhaps not fully appreciated. We have been more and more impressed by the comparatively large number of endonasal conditions unearthed in a systematic search for the cause and relief of a wide variety of ocular disturbances. It is our present intention briefly to point out the more striking and illustrative facts elicited by routine examination and to parallel this with the published reports of other observers, limiting ourselves for the sake of brevity and novelty

to cases seen and reported in the past year or two.

The external eye, the lids, conjunctiva, musculature, episclera and sclera rarely show abnormalities in nasal disease except (1) Local infection in the sinuses is occasionally expressed in conjunctival injection or as an episcleritis or scleritis, or (2) Where an accompanying periostitis of the orbit in ethmoiditis produces an oedema of the lids with proptosis or bulging of the eyeball, together with impaired motility of the globe. Where this periostitis produces a perforation of the orbit with subperiosteal or even orbital abscess, the signs are more intense, going on if unchecked to breaking down of the orbital fascia and skin to spontaneous rupture,

* Read at the Annual Meeting of the Medical Society of the State of New York at New York, March 31, 1926.

nective tissue septum in the shape of a diverticulum into the subdural space carrying blood and lymph channels. This aperture is present up to puberty and sometimes after puberty. This may be of importance from an etiological standpoint.

FIG 3 Oval optic canal, 44×28 mm. Sinuses showed a slight change in illumination of the ethmoids and right antrum. Progressive diminution in vision which improved after treatment.

Roentgenographically, the shadow cast by the canal is referred to as the optic foramen. In reality this shadow is the narrowest portion of the canal. The optic foramen as observed on the film may be circular, oval, triangular or irregular. The shape of the canal can be properly portrayed, if exposed correctly. Faulty technic will alter the appearance of the optic canal, which will be demonstrated later.

Although the question of technique does not properly belong here it is of importance to mention a few words regarding the position of the patient.

The patient is placed in the prone position, the face resting upon the jaw, malar bone and nose for the side rayed. The film is horizontally placed. The central ray is directed perpendicularly to the film. In this manner the optic canal is perpendicular to the film and is projected into the lower and outer quadrant of the orbit. The optic canal is approximately $5\frac{1}{2}$ to $6\frac{1}{2}$ cm above the film. This causes a certain amount of distortion or enlargement of the foramen as it appears in the roentgenogram. In determining the actual diameter of the canal the amount of distortion is taken into consideration. The factors causing the distortion need not be here considered. Tilting of the head in any direction will project the optic canal in some other portion of the orbit; the foramen will appear smaller, the shape will be altered, and the actual measurement misleading. This position was described in a

paper of Dr. White's of Boston, which appeared in the *Boston Medical and Surgical Journal*, November 15th, 1923. Stenver, in 1916, gave considerable attention to the optic foramen, but only studied the size and shape in the roentgenogram in a comparative way, using the Rhese position for the ethmoids. Van de Hoeve did likewise and so did Schuller. Dr. White, however, was the first one to attach any importance to the actual measurements of the optic foramina. Goalwin of New York, determines certain angles for the position of the head and central ray, and also projects the canal in the lower and outer quadrant of the orbit.

White's directions for roentgenography of the optic canal are to be preferred, as the most comfortable for the patient, easiest for radiography, not requiring any accessory devices, and giving uniform results.

A contiguous infection of the optic nerve from adjacent sinuses will only be evidenced by eye manifestations, for there are no roentgenographic changes. Whenever extensive pneumatization exists, it encroaches upon the optic canal, the walls are usually found to be thin, and the diameter diminished. If sinus disease exists, it renders the contents of the canal more susceptible to infection.

The important thing to study in the canal is its size, shape and adjacent disease, if any. The majority of skulls present canals which measure 5 mm or over in diameter, about 10 per cent measure $4\frac{1}{2}$ mm and a very small percentage of the canals measure 4 mm or less in diameter.

The larger canals (5 mm or more in diam-

FIG. 4 Oval optic canal, R. 44×36 mm. L. 48×32 mm. Sinuses showed a slight change in illumination of the left ethmoids and right sphenoid. Visual disturbance. Subsequent developments unknown.

eter) are usually circular, a small percentage being slightly oval or triangular in outline. Of this group, a small percentage show extensive pneumatization. The smaller canals (less than 5 mm in diameter) more than half are oval, triangular or irregular, and the majority of them show extensive pneumatization. An ir-

regular foramen is usually due to variations in development of the skull

Adjacent disease, particularly of the posterior ethmoids and sphenoids, is not always demonstrable. However it is known that sinus disease may exist without clinical or roent-

followed by a persistent fistula. Meanwhile the optic nerve itself may suffer from stretching, or the globe itself by direct infection or by way of the blood stream may become involved in an exudative inflammatory process.

SIMPLE OEDEMA OF THE ORBIT

Case 1—Boy, A. Z., aged 8, seen with Dr. Sidney Yankauer. Intense pain over left eye, with marked swelling of lids, slight proptosis, fundi and media normal. Duration twenty-four hours. Orbital oedema from adjacent acute ethmoiditis. Recommended conservative intranasal treatment for twenty-four hours before considering operation. Eye symptoms quieted promptly.

ORBITAL ABSCESS

Case 2—Infant ten days old, Mt. Sinai, service of Dr. Shick, history of oedema of right lids since second day of life. Examination showed marked oedema of lids with chemosis and proptosis. Temperature, 102, child looked septic. Suggested blood culture. On the following day there was evidence of periostitis of the right femur. Blood culture positive for staphylococcus aureus. Later lung signs and death on seventh day. Autopsy—generalized sepsis with abscess of right antrum perforating into orbit. The impression here was that the antrum was not the primary focus, but was rather secondary to a general infection, cause undetermined.

Case 3—Boy, age 11. Fell ten feet two days before admission. Unconscious ten minutes. Next day intense oedema of left eyelids. Temperature 102, delirium. Examination, O. S. oedema lids, chemosis, proptosis, faint blurring of nerve head. Tentative diagnosis, fracture of base of skull through left ethmoid with beginning orbital abscess. No pus obtained with syringe then. Two days later we aspirated pus from upper inner quadrant of orbit and then opened and drained the abscess. Wound drained, gradually closed but reopened several times. Recommended intranasal exenteration of ethmoid. Unable to convince Rhinologist of this necessity, I reopened orbit, exposed lamina papyracea, demonstrated a fissure fracture therein and proceeded to exenterate the ethmoid from the orbital side. Wound sewed together in two layers, orbital fascia and skin. Primary union, recovery uneventful and complete.

We agree with Dr. Yankauer that ethmoiditis with orbital cellulitis is best attacked by the intranasal route, if seen early enough.

UVEITIS

Iritis, uveitis and chorio-retinitis are comparatively rare as sequelae of sinusitis, but occasionally found. This is particularly important as the possible underlying cause of cataract secondary to uveitis in youth and middle life, as well as a possible source of post-operative infection in all

operations on the globe, which should be eliminated if possible. The routine use of the slit lamp and microscope is proving that many cases regarded as primary glaucoma are in reality secondary to a low grade uveitis and the possible connection with underlying focal infection is pregnant with possibilities of extreme importance. Not rarely a patient will call upon an ophthalmologist complaining of pain over one or both eyes, in whom a history of acute coryza and the finding of tenderness on pressure over the supro-orbital ridge is sufficient to establish a diagnosis of acute frontal sinusitis.

In obscure cases of metastatic choroiditis, the sinuses must be eliminated as a causative factor.

PAPILLEDEMA

Papilledema or choked disc, though most frequently denoting increased intracranial pressure due to tumor, is also occasionally found as a complication of a focal infection, especially lateral sinus thrombosis and accessory sinusitis, diseased tonsils and teeth.

Crigler (33) reports a case of choked disc cured by exenteration of the ethmoids in a girl of nine years. Echavarría (34) reports a case of edema of the optic nerve due to suppuration in the antrum of Highmore.

OPTIC NEURITIS

Optic neuritis, characterized by rapid diminution of vision with redness, blurring of the disc, contraction of the visual fields is frequently due to ethmoid and sphenoid sinusitis.

Case 4—Dr. J. A. C. Headache, photophobia, blurred vision, deep orbital pain. Examination decided blurring of outline of both discs, contraction of color fields with relative scotoma for red in the right eye. No general or focal disease except bi-lateral ethmoiditis. Referred to Dr. Yankauer, who advised ethmoid operation. Patient deferred operation and the symptoms cleared up with nasal irrigation but have a tendency to recur and the man should have his sinuses radically exenterated.

The literature shows seventeen cases reported in the last two years, which probably represents but a fraction of the total. These are on the following page.

RETROBULBAR NEURITIS

Finally and of greatest importance is the question of retrobulbar neuritis, for two reasons, first, because of its greater frequency, and second, because of the absence of any *objective* eye findings to suggest its presence. The conjunctiva, musculature, pupils, media and fundi are normal, yet vision becomes rapidly or slowly diminished often with permanent impairment due to later atrophic changes in the nerve fibers which then and then only become visible with the ophthalmoscope. By retrobulbar neuritis is meant an inflammatory process in the optic nerve or

	No of cases	Resume
Valude & Chantier (1)	1	Cured by operation of both sphenoids, vision returned from light perception to 20/20
Frey (2)	1	Relieved by frontal sinus operation.
Coutela & Veil (3)	2	Unilateral, X-ray negative, cured by sphenoidectomy
Genet & Jacob (4)	2	Posterior sinus involvement, one with complete recovery of vision and one with partial recovery of vision, after operation
Cridland (5)	1	Heterophthalmos, neuro-retinal atrophy secondary to sphenoid sinuses
Temple-Smith (6)	1	Following acute cold, reduction of vision to hand movements entirely relieved by having both sphenoids opened
Grandclement & Sarguon (7)	1	Vision improved from 2/10 to normal in a few days after removal of middle turbinates.
Pakozdy (8)	1	Bilateral, the second eye involved two weeks after the first, cured by ethmoidectomy
Peter (9)	1	Ethmoid and sphenoid sinusitis, caused by operation
Thompson (10)	2	Ethmoid and sphenoid sinusitis, caused by operation
High (11)	1	Left optic neuritis, cured by exenteration of left ethmoid.
Post (12)	2	Cured by sphenoid and ethmoid operation.
Swerdfeger (13)	1	Left optic neuritis, cured by sphenoidectomy

its sheath anywhere along its course from the optic chiasm to the insertion into the globe. Most frequently the trouble is found in the orbital canal wherein the nerve is confined with but small leeway for expansion in inflammatory oedema. As a consequence any increased intracranial pressure is expended upon the delicate nerve fibers themselves and under these circumstances the maculopapular bundle, which innervates the macular region of the retina usually suffers most, due undoubtedly to its greater delicacy of structure. This is evidenced by finding a central scotoma or blind spot in the visual field. The peripheral fibers are also involved sooner or later which produces a concentric contraction of the color fields, with or without involvement of the field for form. The mechanics of the production of retrobulbar neuritis in accessory sinusitis is not entirely clear, but when one considers the proximity of the orbital canal to the sinuses, which last are extremely erratic in their development and extent, so that the nerve may be separated from the mucosa of the sinus by a papyraceous layer of bone only, the obvious deduction of direct infection is most feasible. Gradle, of Chicago, suggests that the infection is carried through venous channels which drain backward into the ophthalmic system. White, of Boston, is sponsor for the ingenious suggestion that retrobulbar neuritis occurs only in those individuals whose optic foramen is abnormally narrow. By roengenological examination he measures this diameter in vitam.

Clinically, retrobulbar neuritis occurs in acute and chronic form. The acute type manifests itself by headache, a rapidly progressive loss of central vision, together with concentric contraction of the peripheral fields, first for color and then for form, also tenderness on pressure upon or movement of the globe. In the chronic form the symptoms are less acute, dull ache or no pain, concentric contraction of the fields with or without central scotoma.

We were impressed by the large number of

patients who in a routine examination, which includes always the charting of the fields of vision, showed definite contraction of the fields for colors alone or with peripheral contraction for form. These cases on further study often showed evidence of sinusitis and regained normal fields after appropriate care of the nasal condition. For some time we seemed alone in the opinion that concentric contraction of the fields without central scotoma is sufficient evidence of a retrobulbar neuritis. Now, however, Gradle has reached the same conclusion as has also Baldenweck of Paris.

ACUTE FORM

Case 5—Mrs. Emil M., referred by Dr. Mark Gottlieb, sole complaint eye fatigue and occasional slight headache, the usual story of the patient seeking relief from eye strain. Examination negative except for hyperopia and astigmatism. Perimetry, however, disclosed marked concentric contraction for both form and color with a large absolute central scotoma in the right eye. General, local and X-ray examinations negative. Referred back to Dr. Gottlieb with recommendation that bilateral ethmoid exenteration be done. Fields entirely normal on re-examination two weeks after operation.

Case 6—Clarence R. T. Six days before examination noticed faint film over left eye, gradually growing worse. Pain in eye on moving it. Examination conjunctivae, pupils, musculature, fundi and media normal. Vision right eye, 20/20, left eye, 4/200, slight tenderness on pressure over the left eye. Right field normal, left concentric contraction with total loss of color perception and a huge absolute central scotoma. Because of the rapidity and extent of the visual damage, an immediate exenteration of the ethmoids was recommended and done at Mt. Sinai within a few hours by Dr. Kaempfer. There were no definite operative findings but vision began to improve in a few hours and in a week scotomata and color blindness had disappeared.

followed by a persistent fistula. Meanwhile the optic nerve itself may suffer from stretching, or the globe itself by direct infection or by way of the blood stream may become involved in an exudative inflammatory process.

SIMPLE OEDEMA OF THE ORBIT

Case 1—Boy, A. Z., aged 8, seen with Dr. Sidney Yankauer. Intense pain over left eye, with marked swelling of lids, slight proptosis, fundi and media normal. Duration twenty-four hours. Orbital oedema from adjacent acute ethmoiditis. Recommended conservative intranasal treatment for twenty-four hours before considering operation. Eye symptoms quieted promptly.

ORBITAL ABSCESS

Case 2—Infant ten days old, Mt. Sinai, service of Dr. Shuck, history of oedema of right lids since second day of life. Examination showed marked oedema of lids with chemosis and proptosis. Temperature, 102, child looked septic. Suggested blood culture. On the following day there was evidence of periostitis of the right femur. Blood culture positive for staphylococcus aureus. Later lung signs and death on seventh day. Autopsy—generalized sepsis with abscess of right antrum perforating into orbit. The impression here was that the antrum was not the primary focus, but was rather secondary to a general infection, cause undetermined.

Case 3—Boy, age 11. Fell ten feet two days before admission. Unconscious ten minutes. Next day intense oedema of left eyelids. Temperature 102, delirium. Examination, O. S. oedema lids, chemosis, proptosis, faint blurring of nerve head. Tentative diagnosis, fracture of base of skull through left ethmoid with beginning orbital abscess. No pus obtained with syringe then. Two days later we aspirated pus from upper inner quadrant of orbit and then opened and drained the abscess. Wound drained, gradually closed but reopened several times. Recommended intranasal exenteration of ethmoid. Unable to convince Rhinologist of this necessity, I reopened orbit, exposed lamina papyracea, demonstrated a fissure fracture therein and proceeded to exenterate the ethmoid from the orbital side. Wound sewed together in two layers, orbital fascia and skin. Primary union, recovery uneventful and complete.

We agree with Dr. Yankauer that ethmoiditis with orbital cellulitis is best attacked by the intranasal route, if seen early enough.

UVEITIS

Iritis, uveitis and chorio-retinitis are comparatively rare as sequelae of sinusitis, but occasionally found. This is particularly important as the possible underlying cause of cataract secondary to uveitis in youth and middle life, as well as a possible source of post-operative infection in all

operations on the globe, which should be eliminated if possible. The routine use of the slit lamp and microscope is proving that many cases regarded as primary glaucoma are in reality secondary to a low grade uveitis and the possible connection with underlying focal infection is pregnant with possibilities of extreme importance. Not rarely a patient will call upon an ophthalmologist complaining of pain over one or both eyes, in whom a history of acute coryza and the finding of tenderness on pressure over the supro-orbital ridge is sufficient to establish a diagnosis of acute frontal sinusitis.

In obscure cases of metastatic choroiditis, the sinuses must be eliminated as a causative factor.

PAPILLEDEMA

Papilledema or choked disc, though most frequently denoting increased intracranial pressure due to tumor, is also occasionally found as a complication of a focal infection, especially lateral sinus thrombosis and accessory sinusitis, diseased tonsils and teeth.

Crigler (33) reports a case of choked disc cured by exenteration of the ethmoids in a girl of nine years. Echavarría (34) reports a case of edema of the optic nerve due to suppuration in the antrum of Highmore.

OPTIC NEURITIS

Optic neuritis, characterized by rapid diminution of vision with redness, blurring of the disc, contraction of the visual fields is frequently due to ethmoid and sphenoid sinusitis.

Case 4—Dr. J. A. C. Headache, photophobia, blurred vision, deep orbital pain. Examination decided blurring of outline of both discs, contraction of color fields with relative scotoma for red in the right eye. No general or focal disease except bi-lateral ethmoiditis. Referred to Dr. Yankauer, who advised ethmoid operation. Patient deferred operation and the symptoms cleared up with nasal irrigation but have a tendency to recur and the man should have his sinuses radically exenterated.

The literature shows seventeen cases reported in the last two years, which probably represents but a fraction of the total. These are on the following page.

RETROBULBAR NEURITIS

Finally and of greatest importance is the question of retrobulbar neuritis, for two reasons, first, because of its greater frequency, and second, because of the absence of any *objective* eye findings to suggest its presence. The conjunctiva, musculature, pupils, media and fundi are normal, yet vision becomes rapidly or slowly diminished often with permanent impairment due to later atrophic changes in the nerve fibers which then and then only become visible with the ophthalmoscope. By retrobulbar neuritis is meant an inflammatory process in the optic nerve or

tumors including an aneurism of the circle of Willis, an hypophyseal cyst, a supra-sellar tumor and two frontal lobe neoplasms. One of the latter we saw with Dr. Elsberg and besides the definite retrobulbar neuritis there was ample neurological evidence of a left anterior fossa new growth, which finding was confirmed by Dr. Elsberg at operation. Three cases were ascribed to malaria, three to toxemia, one of these metastatic, one to wood alcohol, and one to arsenic, ascribed to six doses of salvarsan in two weeks, one to dental infection and nineteen unaccounted for. It is but fair to add that Chaillous (37), Weill (38) and Bourguet (39) report a series of fifteen cases with spontaneous recovery (14 to 44 inclusive).

CONCLUSIONS

First No eye examination is complete without a careful plotting of the visual fields.

Second In the presence of ocular inflammation a thorough search for the underlying cause must be made, including clinical, serological, and roentgenological examinations and the cause, if found, be removed if possible. In addition, in all cases of retrobulbar neuritis, optic neuritis and papilledema a complete neurological examination is indicated in addition.

Third In all cases of retrobulbar neuritis in which no other cause can be found, the ethmoids and sphenoids should be exenterated, even if there is no clinical or roentgenological evidence of sinus disease.

and fields were approaching normal Vision 20/15

CHRONIC FORM

Case 7—Miss B, 18, referred by Dr Mark Gottlieb Chief complaint headaches for one month Examination showed no abnormalities except some fine powdery deposits in the vitreous, visible with slit-lamp microscopy, simple hyperopia and concentric contraction for form and colors in both eyes, more marked in the left, together with a slightly enlarged blind spot in the right eye Glasses were prescribed and conservative intranasal treatment recommended After two weeks fields showed increased constriction and headaches persisted A bi-lateral ethmoidectomy done by Dr Gottlieb and one week later there was marked improvement in the visual fields and the headaches were gone Six weeks later, however, there was a return of headaches and contraction of the fields in the left eye, but after further toilet of the sinuses, there was a complete restoration of the fields and relief from pain

Case 8—Mrs Harold S, 31, referred by Dr Harold Hays Complained of severe headache off and on for three years accompanied by blurring of vision There were frequent attacks of coryza with aggravation of the symptoms Examination showed no objective signs except a moderate amount of latent hyperopia, the correction of which did not relieve the patient's distress Perimetry disclosed concentric contraction for form and colors, without scotomata General physical examination negative, Wassermann negative, teeth normal, and X-ray of sinuses negative We recommended an exenteration of the ethmoids which was done under ether anaesthesia per rectum Within two weeks there was a return to normal of the visual fields and relief from subjective symptoms

Case 9—Mrs Ludwig S, 35 Called for routine eye examination The patient gave a history of repeated attacks of acute sinusitis but had no subjective symptoms of any kind at the time of examination Nothing abnormal was disclosed save an error of refraction and definite contraction of the color fields in both eyes Referred back to Dr Mackenty who stated that our observations convinced him that intranasal operation was now inevitable A radical ethmoid operation was done, after which the color fields improved and the sinus attacks ceased

Case 10—Ida B, 24 Glasses prescribed by an oculist in Atlantic City four weeks before examination After wearing the glasses for a week the patient complained of a blur before the right eye, but was assured that this was to be expected The blurring continued, gradually becoming worse until at present she sees large forms only There was slight orbital pain. On examination there were no objective findings Vision in the right eye was limited to counting fingers

at six feet and could not be improved with glasses Vision in the left eye was 20/20 Perimetry disclosed concentric contraction for form in the right eye and total loss of color perception, in the left eye contraction of the color fields and a small color scotoma Referred to Dr Gottlieb with the recommendation that an ethmoidectomy be done immediately even if the X-ray disclosed no evidence of sinusitis

Six days after operation there was still no improvement On the contrary, the right field was smaller with an absolute central scotoma and the left fields were more contracted On the eleventh day the field for form in the right eye was larger but the central scotoma was still present The left color and form fields were approaching normal and the scotoma was gone. There was slow but definite improvement until, three months after operation, the fields, though somewhat contracted, showed entire absence of scotoma, the vision having been restored to normal with appropriate correction Meanwhile all other general and focal examinations had proved negative The slowness of recovery in this case was undoubtedly due to the three weeks' delay in coming for treatment, the blurred vision having been attributed to the wearing of a new pair of glasses

Case 11—Arnold H, age 25 Complained of dull occipital headache and limitation of visual fields, describing the defect spontaneously as similar to gazing through a narrow tube with each eye, also fatigue after reading but no hemeralopia On examination no objective findings but there was definite concentric contraction of the fields for form and slightly for colors, without any scotoma The vision was 20/15 in each eye with correction General and focal examinations disclosed nothing except diseased tonsils, which latter were removed by Dr Yankauer without any improvement in the eye condition Dr I Strauss reported no neurological findings There was doubtful clinical and X-ray evidence of ethmoiditis, enough to warrant exenteration of the right ethmoid by Dr Yankauer One week later the fields were normal Six weeks after operation there was recurrence of headache and of marked contraction of the visual fields in the left eye A submucous resection of the septum, together with an ethmoidectomy on the opposite side, failed to restore the visual fields

Adding our cases to those found in the published reports of the last two years, the following facts are elicited Of a total number of 124 cases of retrobulbar neuritis, those due to endonasal causes were 53 or over 40 per cent, and in all these cases where any mention of therapeutics was made recovery followed operative interference Forty cases were attributed to multiple sclerosis, of which several were not definite, the diagnosis having been made upon very meager grounds, 5 cases due to intracranial

tumors including an aneurism of the circle of Willis, an hypophyseal cyst, a supra-sellar tumor and two frontal lobe neoplasms. One of the latter we saw with Dr. Elsberg and besides the definite retrobulbar neuritis there was ample neurological evidence of a left anterior fossa new growth, which finding was confirmed by Dr. Elsberg at operation. Three cases were ascribed to malaria, three to toxemia, one of these metastatic, one to wood alcohol, and one to arsenic, ascribed to six doses of salvarsan in two weeks, one to dental infection and nineteen unaccounted for. It is but fair to add that Chaillous (37), Weill (38) and Bourguet (39) report a series of fifteen cases with spontaneous recovery (14 to 44 inclusive).

CONCLUSIONS

First No eye examination is complete without a careful plotting of the visual fields.

Second In the presence of ocular inflammation a thorough search for the underlying cause must be made, including clinical, serological, and roentgenological examinations and the cause, if found, be removed if possible. In addition, in all cases of retrobulbar neuritis, optic neuritis and papilledema a complete neurological examination is indicated in addition.

Third In all cases of retrobulbar neuritis in which no other cause can be found, the ethmoids and sphenoids should be extirpated, even if there is no clinical or roentgenological evidence of sinus disease.

POSTINFLUENZAL DISTURBANCES OF THE HEART*

By ALBERT S. HYMAN, M.D., NEW YORK

DISTURBANCES of the cardiovascular system developing in the course of a severe general infectious disease is not an unfamiliar clinical picture to most physicians. As long ago as 1884, Alonzo Clark (1) in his lectures to the students at the College of Physicians and Surgeons in New York pointed out that such infectious diseases as typhoid fever and sore throat may leave an indelible imprint upon the functional integrity of the heart and its vascular system.

The attention focused by MacKenzie (2) upon the reactions of the myocardium to other infectious diseases which "poisoned" the heart soon brought to light the menace associated with conditions generally considered to be relatively innocuous. Diphtheria (3), typhus fever (4), certain types of pneumonia (5), and acute rheumatic fever (6) were found to be responsible for cardiac damage manifesting itself subsequent to the original infective process.

With the development and increasing refinement in the established methods of cardiovascular study, electrocardiographic and functional investigation of the heart have demonstrated important changes which were hitherto not discoverable by the usual clinical methods of examination. Many of the so-called "childhood diseases" and other infective conditions have been re-investigated with the alarming conclusion that myocardial damage is not an infrequent accompaniment of even the mildest type of general infection. A recent study by Hoskins (7) of London indicates how delayed myocardial repair may be after the subsidence of the original infection, in a series of 16 cases of diphtheria which were carefully followed, myocardial mischief was demonstrable by electrocardiographic methods as long as 86 days afterwards.

Attention has lately been directed to the cardiac sequelae of what is undoubtedly the most widespread of all the infectious diseases—influenza. Beginning with the pandemic in 1918-19, the various complications developing during or subsequent to an acute influenzal attack have been carefully scrutinized by investigators of the problem

throughout the world with a resulting literature which is especially voluminous, practically every organ of the body has been studied in relation to this disease.

Yet with all the accumulated information which has been noted, it is rather astonishing to find how little attention has been devoted toward the purely cardiovascular aspect of the influenzal affections. It is the humble purpose of this paper, therefore, to attempt to summarize briefly the more important conceptions which we have made in our investigations of this matter at the Witkin Foundation for the Study and Prevention of Heart Disease at the Beth David Hospital, New York.

Although Field (8) has properly raised the question as to the accuracy of the diagnosis, we have assumed the usual symptom complex of fever, malaise, generalized pains and aches, coryza and other upper respiratory tract irritation, headache, and nausea to be clinically suggestive of an influenzal attack.

Unless the toxæmia be extreme or there has been a previous damage sustained by the myocardium, ordinarily no disturbance of the heart is noted until the third or fourth day of the infection. From this time onward, cardiac affections are prone to occur with increasing frequency up to ten days or two weeks after the onset of the disease.

The actual incidence of myocardial disease as the result of influenzal infection has been somewhat difficult to determine. Rehfish of Berlin, in whose clinic I had the privilege of studying a series of postinfluenzal conduction disturbances of the heart, estimated that about 7% of all influenzal infections showed cardiac mischief. Parsons-Smith of the Heart Hospital in London believed that the figure ran about 5% in England. My own figures are taken from two series: the first of 231 cases collected in 1918-19 at the Long Island Hospital, Boston, with an incidence of about 12%, the second group studied during the winter and spring of 1925-26 of 61 cases with an incidence of 4%. The relatively high incidence in the first group may in part be due to the severity of the infection during the pandemic, and

* From the Witkin Foundation for the Study and Prevention of Heart Disease at the Beth David Hospital.

secondly, that the group consisted of more elderly persons than in the recent series. However, we shall not probably be far amiss in assuming that from 4% to 6% of all influenzal infections carry with them the hazard of myocardial damage.

In our experience, postinfluenzal cardiac mischief can be clinically divided into three easily distinguished groups: (1) those with irregularities of rhythm, (2) those with endocardial and valvular changes, and (3) those with manifest signs of decompensation. Not uncommonly the three groups tend to be present together in a given case, each in a varying degree of severity.

Of the three groups, the first is undoubtedly the most frequent. Irregularities of the heart beat with its disturbance of rhythm is readily detectable by the physician in the most simple examination of the heart. When studied by polygraphic or electrocardiographic methods such irregularities are usually found to be due to extra systoles or premature beats, gross perversions of the mechanism of the heart beat like auricular flutter and fibrillation, and finally, depression of the conducting system resulting in the three degrees of heart block.

Concerning extra systoles, little need be said, they are nearly always due to extra-nodal points of irritability which arise in the myocardial tissue during any severe toxæmia. They tend to disappear and are not particularly serious unless they occur with such a frequency as in paroxysmal tachycardia, as to interfere with the proper filling of the left ventricle with subsequent circulatory deficit.

Gross perversions of the pace maker mechanism with the onset of auricular flutter or fibrillation constitutes a hazard which may rapidly terminate in circulatory failure. The process in these cases bears a strong resemblance to that developing in thyrotoxicosis, and it challenges the best methods of therapy for the preservation of life.

Heart block or depression of the conducting system is not an uncommon discovery in postinfluenzal hearts. I have recently published (9) a series of cases demonstrating the three degrees of heart block which may occur. First degree or lengthening of the P-R interval in the electrocardiographic tracing represents a delay in the transmission of the impulse from the auricle to the ventricle. Such cases can only be diagnosed by instrumental methods, but it is of interest to note at this time that such changes are probably more frequent than we have had previous reason to suspect, especially in the very mild or "missed" cases of influenza. In one case which I quote, the original influenzal attack was only of three days duration but cardiac mischief was demonstrable for more than four months.

A further depression of the conducting system results in so-called second degree or partial heart block. In these cases an intermission is noted in

the pulse at the wrist, and upon careful scrutiny the jugular pulsations in the neck are found to be perfectly regular. It can be determined that every third, fourth, or fifth beat is dropped out and a diagnosis of 4 to 3, or 5 to 4 or other numerical rhythm can be correctly established without instrumental assistance. Such partial heart block is usually not permanent, it may appear and disappear in a single day. Its discovery, however, during or after an influenzal attack may be regarded as ominous.

Complete heart block representing a third degree of conduction disturbance with independent auricular and ventricular rhythms is of especial prognostic import. Clinically known as the Adams-Stokes syndrome it usually indicates considerable and often irremediable myocardial damage. While I have never seen it develop in a sound heart during an attack of influenza, patients who have been suffering from myocardial disease may be prone to its occurrence. In the case reported by me (9) return to the original condition required four months of carefully supervised convalescence.

All such irregularities of rhythm as extra systoles, perversions of the pace maker mechanism, and depression of the conducting system occurring during or subsequent to an acute influenzal infection must thus be regarded as evidence of myocardial damage which is often out of proportion to the severity of the acute attack itself. Of special note in this connection is the relatively long period of time required for myocardial repair. A suggestion is thus presented in the regulation of a patient's postinfluenzal convalescence when such disturbances are noted.

The second large group of postinfluenzal effects upon the cardiovascular system is the endocardial manifestation of the disease. Until recently little attention has been directed toward this aspect of the problem. Oppenheimer (10) writing in the Bulletin of the Johns Hopkins Hospital in May of this year describes a case of influenzal bacillus endocarditis which followed a course typical of the more common viridans endocarditis. The blood cultures in this case showed the Pfeiffer bacillus in large colonies. At post mortem, the verrucous vegetations upon the thickened and inflamed valves resembled in many ways the streptococcal viridans disease.

While this condition is apparently uncommon, I have noted one case in my series which undoubtedly suffered valvular disease of a type usually associated with an acute rheumatic infection. A question has arisen whether many endocardial conditions now attributed to a rheumatic origin may not in fact be the result of an influenzal disease in as much as the bone and joint pain believed to be so characteristic of rheumatic affection may also occur in severe influenzal attacks. With closer study, I believe that this group of

influenzal sequelae will assume more importance than in the past

Finally, we have to consider the group of post-influenzal affections resulting in circulatory failure. In this group must be placed the acutely dilated hearts and those cases which show unmistakable evidence of vascular collapse. Acute dilation of the heart while frequently diagnosed is probably not quite so common as was formerly assumed. Ordinarily, the clinical diagnosis is based upon a widened area of percussed cardiac dullness, but when checked by subsequent orthodiagraphic measurements the anticipated increase in the size of the cardiac shadow is not found. Kovács of Vienna has pointed out that the area of cardiac dullness increases faster than the actual widening of the heart itself, this is due to a well established principle of acoustics applied to a circular chamber like the chest.

Relative widening of the heart due to toxæmic myocarditis is usually not seen until after the first week of the disease. All of the dilatation phenomena may be present—tachycardia, mitral and aortic regurgitant murmurs, diffuse apex beat, asynchronism of the valve closures, and if the dilation is great enough to cause axial rotation of the heart, there may be posterior transmission of the heart sounds. Such cases when studied by electrocardiographic methods frequently show QRS-complex changes suggestive of serious myocardial damage.

Cardiovascular collapse with cold and clammy extremities and a generalized cutaneous cyanosis was one of the tragic phases of influenzal infection too often encountered during the great pandemic, every physician can recall these cases quite distinctly so characteristic was the bedside picture. It was believed at the time that the condition was due to widespread and rapidly fulminating pulmonary involvement, an extreme blueness and signs of a severe toxæmia developed early in the attack, sometimes as soon as the second or third day, long before any signs were clinically discoverable in the chest. The name "blue pneumonia" carried an ominous prognosis, for many patients showing this syndrome ran a very short fatal course. I am of the opinion that many of these cases were due to *specific poisoning* of the entire cardiovascular system by the virulent type of influenzal organism present at the time. While it is true that considerable attention has been focused upon the pulmonary involve-

ment associated with this type of case, post mortem examination of the lungs failed to show any close correspondence between the pneumonic process present and the degree of toxæmia and cyanosis occurring during life. Study of the cardiovascular aspect of these cases promises to yield more than that obtained from the many investigations concerned with the purely pulmonary factor of the disease.

SUMMARY

1 Influenza must be placed among those infectious conditions which may cause cardiac mischief.

2 Approximately 4 to 6% of all cases of influenza show subsequent disturbances of the heart.

3 These disturbances are of three general types: (1) irregularities of rhythm, (2) endocardial and valvular affections, and (3) cardiovascular collapse.

4 The severity of the original influenzal attack bears little or no relation to the extent of the cardiac damage.

5 The repair of the cardiac mischief is very slow and it is apparently out of proportion to the extent of the damage discovered.

6 If cardiovascular symptoms appear during or after an attack of influenza, convalescence should be extended until all demonstrable evidence of the affection has disappeared.

THE PRIVATE PRACTICE OF PREVENTIVE MEDICINE

By PAUL B. BROOKS, M.D.

Deputy State Commissioner of Health Albany, N. Y.

Summary of a Talk before Schoharie County Medical Society, October 19, 1926

THE tremendous development of public health work in the past 25 years has led to the fear on the part of some physicians that their practice will be seriously encroached upon, and that a hydra-headed monster called 'state medicine' is developing and will ultimately become a serious menace. It is a fact that owing to the marked decline in the prevalence of communicable diseases, the diarrheal and other disorders of infants, etc., physicians are attending many less cases of certain kinds than they were thirty years ago. However, as will be pointed out later, there is a compensatory factor if the physician will take advantage of present opportunities.

As for "state medicine," while various public officials and agencies are doing work, such as vaccination against smallpox, administration of toxin-antitoxin, treatment of venereal diseases, and physical examination of school children, all of which strictly speaking is practice of medicine, they are doing these things simply because they are in the interest of public health and it is the duty of "the state" to do them until private agencies, including the practitioners of medicine, are willing and ready to take them over.

Speaking for the State Department of Health, there is no desire or intention to control or take part in the practice of medicine in the state. While, for example, our district state health officers from apparent necessity devote some of their time to administering toxin-antitoxin, we would much prefer that this be done by others so that their entire attention could be given to their numerous administrative duties.

The conflict of interests of the medical profession and the public health agencies is apparent, and not real. The situation demands a readjustment of our conception of medical practice, and possibly also of our ideas of medical ethics. When such adjustment has been brought about, the situation can be met to the mutual advantage of the physician and the public.

The *Buffalo Courier-Express* for October 13th contained one of Glenn Frank's syndicated editorials, this one on "Doctors as Health Masters." Mr. Frank was formerly editor of the *Century Magazine*, is now a College president and a man who is likely to talk sense. He said in substance that if the American people would look to their doctors for the care of their health rather than for the cure of disease "a wholly new order could be established in the world of medicine." The family would secure the doctor's services by the year rather than by the visit, the physicians would endeavor by various means to keep the members of the family well, and would be called at the first hint of sickness rather than after the in-

dividual is seriously ill. He said, "No one knows the number of crippled bodies and cowed spirits that are dragging through life because they dithered and delayed about calling the doctor." The physician could call as often as necessary and stick to a case as long as necessary" without being accused of tee hunting. "Many distinguished doctors" have declared this to be a practical proposition.

At present we wait until sickness occurs. This plan is uneconomical, and at times the illness results in permanent damage which might have been prevented. The public will ultimately see the logic in the old adage that an ounce of prevention is worth a pound of cure, and will be willing to pay at least as well for the ounce of prevention as they are now paying for the pound of cure.

It would seem that a physician who was so inclined could develop a paying practice made up largely of preventive work. The individual who entered into the contract such as Mr. Frank suggests would be providing for himself an insurance against sickness. It will undoubtedly be some time before any such plan will be generally adopted, but in the meantime it is practicable for the private practitioner to practice preventive medicine in connection with his general practice.

There are many things that a physician can do in this line. Some of them are here divided for convenience into three groups:

- 1 Protective inoculations
- 2 Periodic health examinations
- 3 "Other things"

The administration of protective inoculations is simple, requiring no special preparation on the part of the physician. Smallpox vaccination and the administration of toxin-antitoxin are the ones which are outstanding just now. The State Medical Society, the State Department of Health and other organizations have initiated a campaign against diphtheria in connection with which an effort is being made to secure the immunization of the largest possible number of children under ten years of age. The Department is constantly advising people that they take their children to their own physicians for immunization, and the medical society in various ways is trying to interest physicians in doing this work. The toxin-antitoxin is furnished without charge by the department, and a great many people are able—and if converted to the idea would be willing—to pay for this service.

While the Department advises people to go to their own physicians, its primary aim is to secure the protection of the children and the eradication

of diphtheria. We believe that if the children and the family physicians fail to "connect," it is the duty of local health officials to see that the immunizations are provided without unnecessary delay.

When this subject was discussed before two other county medical societies, it was discovered that very few physicians were doing any of this work in their private practices. It would appear that the doctors not only are neglected an opportunity to do a kind of work which is simple and should be reasonably lucrative, but possibly there are also neglecting a duty to their constituents in failing to advise them to bring their children for immunization. We refer to the "five-year campaign." The truth is that immunization against diphtheria is a permanent institution. It will never be done on a sufficiently large scale to make it thoroughly effective unless the general practitioners take it up as a definite feature of practice. Many county medical societies have adopted resolutions endorsing the campaign, but that is not enough.

Group No. 2 was "periodic health examinations." This means examining apparently healthy individuals with a view to discovering defects and slight departures from normal while they are still remediable and giving advice as to how to correct them. While detection of slight abnormalities and advising as to their correction is quite different from diagnosing an obvious illness and prescribing treatment and requires some study and adaptation, it is nevertheless something that any intelligent physician can do if he will.

For convenience I have divided the individuals who should have such examinations into three classes—preschool children, school children, and adults. The department is conducting, mostly in rural sections of the state, what it calls "children's consultations." Children apparently well and mostly of preschool age are given a simple routine examination designed to discover defects. When defects requiring treatment are found, the parents are advised to take the children to their own physicians. Over 2000 children were so referred last year. The idea is not so much to get the children examined as to disseminate the idea of taking children regularly to physicians for such examinations. It is really only a demonstration, and it is always our hope that the work will be taken over by the local physicians. Incidentally, several physicians have told us that their practice among children was increased after the "consultations" had been held in their communities. If the defects were discovered and corrected in the preschool children, there would be no occasion for discussing the next group, namely, the school children.

The State Education Law requires every school district to provide for an annual physician examination of all school children, excepting those who are examined by their own physicians.

Sometimes these examinations are carefully made, sometimes very poorly, but there is no doubt that generally speaking this system has resulted in improved health and scholarship among school children. The family doctor could just as well be making these examinations, but he is doing it mostly in isolated instances. Lack of interest on the part of the medical profession is, at least in part, accountable. When, as occasionally happens, a parent sends a school child to the family physician with the school examination blank, the physician is too apt to look upon this as a more or less foolish requirement and to fill out the blank in a perfunctory way, entirely overlooking the fact that the examination should be of real value to the child. There is little doubt in my mind but that boards of education would much prefer to encourage the parents able to pay to take their children to their own doctors instead of having them examined by the school physician, if they could be reasonably assured that the examinations would be made with care and thoroughness. It would save money for the school district and increase the practice of the physicians.

The department through its radio health talks and in other ways is constantly advising adults to go to their physicians periodically for "health examinations." A few years ago we sent out to the physicians of the state, outside of New York City, sample copies of the American Medical Association health examination blank with letters urging the physicians to be prepared to make the examinations when people applied for them. Several county medical societies have adopted resolutions endorsing the idea, but apparently few physicians take it seriously insofar as their own practices are concerned. One of our representatives who spends her time giving health talks to women in rural communities always advises these women to have such examinations made. On more than one occasion on going back to a community she has been told by some of these women that, after hearing her talk, they had gone to their doctors and asked to be examined, but that the doctors had treated the subject lightly, telling them that there was nothing wrong with them and that they did not need examinations. A former president of the State Medical Society in my presence said that with no thought of "stirring up business" he had explained the health examination idea to a group of men when he met them in a social way. Not long afterward some of them came in requesting examinations. No doubt each of them paid him a reasonable fee. It would not be difficult to conceive of a practice being made up quite largely of this kind of work which should be both pleasant and fairly lucrative. A physician could afford to examine a poor person now and then without charge for the sake of experience.

As to the "other things" which the physician could do in this line I will not take the time to

enumerate them, but there are several which could be mentioned

The very practical question that arises is this Can people be prevailed upon to go to their physicians for this kind of service and to pay for it? I have already cited the experience of one physician If he could interest his friends in a matter of this kind, other physicians could do it It is a well known principle in advertising that people can be led to do almost anything within reason if you keep the idea constantly before them We are willing to do our best to promote the idea if the physicians will do their part However, any storekeeper knows that if he advertises a sale and then fails to produce the goods, it will not be long before his advertisements will be disregarded It is equally true here

It is a question whether physicians are not allowing themselves to be hampered in connection with this work by too rigid adherence to a code of ethics, some features of which may be out-

grown He hesitates to do anything which might be construed as stirring up business As far as preventive medicine is concerned, I believe he is failing to do his duty both to his client and to himself unless he points out to those who look to him for advice the importance of having these things done For example, I believe not only that it is justifiable but that it is his duty to invite the heads of families who ordinarily come to him to send their children in for immunization against diphtheria He should "get off his high horse" in the common interest

In conclusion, if public health work is taking away something from the doctor's practice, it is putting something in its place if he is willing and ready to accept it He has an opportunity to improve his practice and perform a public service at the same time By following this course it is not impossible that the modern physician might again become the "family adviser" like the doctor of the old school

HOW MUCH OF THE INVESTIGATION ON THE SUBJECT OF REJUVENATION IS SCIENTIFIC?

By WILLIAM WOLF, M.D., Sc.D., Ph.D., NEW YORK CITY

REJUVENATION is no new subject The search for lifelong youth or regaining youth which has been lost is many centuries old. The literature on this topic, both scientific and fanciful, is most abundant Some of the writings report carefully controlled experiments, others are entirely unscientific and sometimes fictitious

Many of the authors, and particularly newspaper writers, are entirely incompetent to discuss their subject Human interest and a tendency to dramatic exaggeration seem to be their guides, rather than cold, hard facts The result is that the gullible public is readily misled

There seem to be three principal reasons for the general misunderstanding as to the true status of rejuvenation In the first place, newspaper reporters, reading an article in some medical journal dealing with this subject are too prone to link the actual facts with some fairy tale that they read in their childhood with the result that, instead of a sober report of certain histological and physiological changes observed, for instance, after trying the vas deferens, they turn out a thrilling story of how some decrepit, old man was restored to the appearance and vigor of dashing youth by means of a simple operation or the implantation of "monkey glands" (a favorite term among the general public) Thus the established experiments of science become confused with the shady speculation of monkey gland therapy, with the result that the entire subject is brought into discredit.

A second reason is that aging is a rather in-

definite entity showing manifestations in widely different parts of the body and producing widely different effects in the same part of the body Whenever we have to deal with such a condition confusion is inevitable and, unless the problem is split up into definite entities, semi or non-scientific writers and workers are quick to grasp the opportunity for their own ends thereby causing still greater confusion This has never failed to happen whenever a fad has come into vogue or whenever the relationship of a local condition is linked up indefinitely with the general condition of the body We do not need to search very far for examples We all had to suffer from overzealousness in appendectomies, tonsillectomies, tooth extractions, cancer treatments, etc.

The third cause of confusion is a misunderstanding as to exactly what is meant by the term "rejuvenation" If this term were clearly defined, much of this confusion with regard to this subject would disappear It is, therefore, in order to discuss the meaning of the word

There are four different points of view from which rejuvenation may be considered

- (1) Rejuvenation of the external appearance,
- (2) Restoration of diseased organs to health,
- (3) Mental rejuvenation,
- (4) Cellular rejuvenation.

(1) By rejuvenation of the external appearance is meant the application of measures to make the skin smooth and healthy looking We may in-

clude the use of massage, astringent creams and lotions and other cosmetics. In this group also may be mentioned various beauty specialty operations, such as lifting the skin of the face and neck, and exercises for the reduction of weight.

At times, this external rejuvenation is fairly successful, but we must remember that not only the face and neck but also the hands, arms, and breasts show signs of age. These latter regions must also be treated, otherwise, the artificiality of the subject's youth will be obvious. Furthermore, if youth is to be simulated, we must take into consideration the subject's carriage and conversational voice. The old person has a manner of walking and a pitch and quality of voice that stamp his age. These attributes also must be modified. Although it is alleged that, when a person looks younger, he feels, acts, and actually is younger, most of us will agree that the rejuvenation of the external appearance is merely a makeshift and does not materially lengthen the span of youthful and useful life or actually make the body younger.

(2) The second method of rejuvenation aims to bring the organs of the body to a healthy condition and maintain them in this state. The entire body economy is dependent principally on a properly adjusted intake of food and air (and possibly mental influences) and a proportionate elimination of waste products.

The above contention is borne out by a well known experiment conducted at the Rockefeller Institute. A strain of fibroblasts obtained from an embryo chicken heart has been kept alive for more than ten years outside of the body by immersing it in a suitable culture medium, feeding it regularly with nutrient solution, and renewing the medium so as to provide for tissue elimination. This experiment has been fully described by Ebeling.¹

On the basis of these premises, it may be assumed that the organs of the body may be kept young by keeping the organs of intake (upper gastro-intestinal tract, respiratory and nervous systems) and those of elimination (urinary system, lower gastro-intestinal tract, skin and respiratory system) in perfect working order.

The other parts of the body, namely the muscles, bones, genital tract, circulatory system, etc., may be considered as the framework and accessory paths necessary to support and provide for the activity of the vital organs of nutrition, elimination, and reproduction, while the endocrine system acts as a governing and synchronizing system to see that each organ performs its function properly and to the best advantage for body economy. Their importance, from the standpoint of rejuvenation, lies solely in the fact that, without them, the organs of reception and rejection would be unable to exist and the species could no longer propagate its kind.

(3) Mental rejuvenation, the third phase of this

topic, is based on the conception that, if one thinks in terms of youth, health, vigor and strength, the whole body will adapt itself to that point of view and produce a mental and nervous equilibrium that will allow the various organs to function perfectly. This general principle is utilized, to a large degree, by the various cults of mental healers. Many of them base their methods on religious precepts and in some instances where the author has come in personal contact with East Indians certain individuals have succeeded in appearing, acting and feeling like others one-third their age. This subject is fully discussed by Paulsen² in a series of articles in the *Journal of the American Medical Association*.

(4) The fourth conception of rejuvenation rests on the foundation of the cellular structure of the body. To understand cellular rejuvenation, let us consider the life cycle of one of the simplest forms of animal life, namely, the paramoecium (slipper animal).

As is well known, the paramoecium, a unicellular animal has two methods of reproduction,³ namely (1) direct reproduction or fission and (2) indirect reproduction or copulation. The usual form is by fission, that is, the animal cell simply breaks into two bodies, which become independent organisms. Reproduction by fission may take place for from five to twenty generations, but, thereafter, the paramoecia die unless copulation occurs. During this process two of the animals join and some of their protoplasm is exchanged. Consequently, each of the two forms that result contains elements derived from two parent cells, whereas, when reproduction takes place by fission, there is but one parent cell.

When two paramoecia conjugate, definite changes take place in their micronuclei, whereby each organism receives a fragment of the other's nuclear substance. Preceding this exchange of nuclear material a complicated series of changes takes place in the intracellular substance of the animals that are about to conjugate. As a consequence of conjugation, there is a definite fusion of the residual nuclear material with that derived from the other animal. The result is that an entirely new micronucleus is formed. After the two paramoecia have exchanged nuclear substance, the animals separate. After copulation reproduction by fission may take place for from five to twenty generations more. Woodruff⁴ has cultivated them for more than fourteen years. In many respects, this organism may be considered as potentially immortal.

A system of reproduction somewhat similar to that of the paramoecium has been observed in animals a little higher in the evolutionary scale according to Pearl,⁵ a few of the simplest and least organized groups of the metazoa have a power of multiplication by simple fission, whereby a portion of the organism buds off and gives rise to a new form.

It would seem, that, during the exchange of protoplasm, a true rejuvenation is brought about, that is, the vitality of the cell is brought to the same state in which it was ten generations or so previously.

To my knowledge no life cycle of the type exhibited by the paramoecium has been observed in the cells composing the organism of man or the higher animals, but it is clear that a physico-chemical or bio-chemical reaction is started or brought about which differs from that going on in the aged animal. To find out what this reaction is should be the task for the competent research workers.

This subject would also take in the question of inert materials within the cell. It is a well known fact that cells of an aged subject or animal contain a considerably greater amount of intracellular burden material than those of a younger one. Also, the kind of inert matter seems different. This fact can be observed even grossly as many surgeons have noticed during operations.

How, then, could a true rejuvenation be brought about? If by some means we can stimulate or cause intracellular chemical changes to occur analogous to those above-mentioned, and if we can prevent the deposition of inert material within the cell and between the cells, and if we can prevent formation and absorption of toxins which make proper nourishment and elimination difficult, we have made a very decided step in the right direction.

In other words, there is no reason why the cells of the human body and their combinations should not be able to renew their vitality in the same manner as the paramoecium if it can be found what constitutes aging of the cells and their constituent parts and how this process can be prevented. This study should form the basis of research in the subject of rejuvenation.

It seems to me that the use of the term rejuvenation should be restricted to the cellular conception. Such a clear definition of the term would do much to bring the subject into the realm of science and out of that of fiction and charlatanism.

The first three viewpoints of "rejuvenation" discussed should be called *invigoration* or *bodily improvement*. The use of the term rejuvenation to describe these methods of treatment is incorrect, misleading, and ambiguous and offers too great a temptation to fiction writers and quacks.

To my mind, all scientific study with regard to true rejuvenation should be conducted with a view to bring groups of cells, the cells and their constituent parts, back to the state of vitality that they enjoyed a certain number of generations previously. At least, one should attempt to renew the vitality of the cells and so prevent or delay their aging so that the various cellular combinations which compose tissues will not be subject to disintegration.

The form of rejuvenation that is alleged to be induced by ligation or section of the vas deferens requires discussion. It has been stated by Steinach and Schmidt⁶ that, as a result of this procedure the germinal cells atrophy, spermatogenesis is largely inhibited, and the interstitial cells of Leydig increase in number and activity. As these interstitial cells are reputed to elaborate the hormone responsible for the libido and the development of the secondary sexual characteristics, it is apparent that an influx of their secretion into the blood stream should change the endocrine balance of the body. According to Steinach's⁷ reports ligation of the vas deferens has, in a certain proportion of cases, increased activity and sexual vigor for periods lasting from six months to several years.

In many of the animal experiments with ligation of the vas deferens, results, while promising, have not been permanent. For example, Macht and Teagarden⁸ of Johns Hopkins University, performed ligations on six senescent rats. There was distinct improvement in the general appearance and behavior of the animals. They were more active, and some of them developed a new coat of fur. However, the improvement lasted only for few weeks, after which the animals lapsed into their former aged condition.

According to Oslund⁹, the idea of bringing about rejuvenation by means of ligation of the vas deferens had its origin in experiments on rabbits, rats and guinea pigs. However, there has been one serious error in these experiments. The changes after this operation, according to Oslund are due, not to vasectomy, but to artificial cryptorchidism. In operations on dogs in which Oslund was very careful not to leave the testes in an unfavorable location, degeneration of the germinal cells did not follow. Following such vasectomy, the interstitial cells were normal both as to number and appearance.

In the case of women and female animals, similar results¹⁰ have been reported after subjecting the ovarian parenchyma to the action of X-ray or diathermic electric currents. This was done with the idea to allow the subjacent ovarian substance to increase in size and activity. Recently the writer has applied gamma rays of radium for the same purpose. The results have been considerably better and more permanent than those from tying off the spermatic duct in the male.

Writers who have been impressed with the "rejuvenating" influence of the internal secretions of the sexual glands have applied to the interstitial cells supposed to be responsible for these secretions the picturesque name of "puberty gland." It is doubtful, though, whether there is such a thing as a puberty gland, that is, whether the interstitial cells of Leydig actually do give off an internal secretion. Steffen,¹¹ of Leipzig, who has made a thorough investigation of the subject

clude the use of massage, astringent creams and lotions and other cosmetics. In this group also may be mentioned various beauty specialty operations, such as lifting the skin of the face and neck, and exercises for the reduction of weight.

At times, this external rejuvenation is fairly successful, but we must remember that not only the face and neck but also the hands, arms, and breasts show signs of age. These latter regions must also be treated, otherwise, the artificiality of the subject's youth will be obvious. Furthermore, if youth is to be simulated, we must take into consideration the subject's carriage and conversational voice. The old person has a manner of walking and a pitch and quality of voice that stamp his age. These attributes also must be modified. Although it is alleged that, when a person looks younger, he feels, acts, and actually is younger, most of us will agree that the rejuvenation of the external appearance is merely a makeshift and does not materially lengthen the span of youthful and useful life or actually make the body younger.

(2) The second method of rejuvenation aims to bring the organs of the body to a healthy condition and maintain them in this state. The entire body economy is dependent principally on a properly adjusted intake of food and air (and possibly mental influences) and a proportionate elimination of waste products.

The above contention is borne out by a well known experiment conducted at the Rockefeller Institute. A strain of fibroblasts obtained from an embryo chicken heart has been kept alive for more than ten years outside of the body by immersing it in a suitable culture medium, feeding it regularly with nutrient solution, and renewing the medium so as to provide for tissue elimination. This experiment has been fully described by Ebeling.¹

On the basis of these premises, it may be assumed that the organs of the body may be kept young by keeping the organs of intake (upper gastro-intestinal tract, respiratory and nervous systems) and those of elimination (urinary system, lower gastro-intestinal tract, skin and respiratory system) in perfect working order.

The other parts of the body, namely the muscles, bones, genital tract, circulatory system, etc., may be considered as the framework and accessory paths necessary to support and provide for the activity of the vital organs of nutrition, elimination, and reproduction, while the endocrine system acts as a governing and synchronizing system to see that each organ performs its function properly and to the best advantage for body economy. Their importance, from the standpoint of rejuvenation, lies solely in the fact that, without them, the organs of reception and rejection would be unable to exist and the species could no longer propagate its kind.

(3) Mental rejuvenation, the third phase of this

topic, is based on the conception that, if one thinks in terms of youth, health, vigor and strength, the whole body will adapt itself to that point of view and produce a mental and nervous equilibrium that will allow the various organs to function perfectly. This general principle is utilized, to a large degree, by the various cults of mental healers. Many of them base their methods on religious precepts and in some instances where the author has come in personal contact with East Indians certain individuals have succeeded in appearing, acting and feeling like others one-third their age. This subject is fully discussed by Paulsen² in a series of articles in the *Journal of the American Medical Association*.

(4) The four conception of rejuvenation rests on the foundation of the cellular structure of the body. To understand cellular rejuvenation, let us consider the life cycle of one of the simplest forms of animal life, namely, the paramoecium (slipper animal).

As is well known, the paramoecium, a unicellular animal has two methods of reproduction,³ namely (1) direct reproduction or fission and (2) indirect reproduction or copulation. The usual form is by fission, that is, the animal cell simply breaks into two bodies, which become independent organisms. Reproduction by fission may take place for from five to twenty generations, but, thereafter, the paramoecia die unless copulation occurs. During this process two of the animals join and some of their protoplasm is exchanged. Consequently, each of the two forms that result contains elements derived from two parent cells, whereas, when reproduction takes place by fission, there is but one parent cell.

When two paramoecia conjugate, definite changes take place in their micronuclei, whereby each organism receives a fragment of the other's nuclear substance. Preceding this exchange of nuclear material a complicated series of changes takes place in the intracellular substance of the animals that are about to conjugate. As a consequence of conjugation, there is a definite fusion of the residual nuclear material with that derived from the other animal. The result is that an entirely new micronucleus is formed. After the two paramoecia have exchanged nuclear substance, the animals separate. After copulation, reproduction by fission may take place for from five to twenty generations more. Woodruff⁴ has cultivated them for more than fourteen years. In many respects, this organism may be considered as potentially immortal.

A system of reproduction somewhat similar to that of the paramoecium has been observed in animals a little higher in the evolutionary scale according to Pearl,⁵ a few of the simplest and least organized groups of the metazoa have a power of multiplication by simple fission, whereby a portion of the organism buds off and gives rise to a new form.

origin result from injuries to the vaginal walls, subjacent structures and cervix

The diagnosis of bleeding from *external causes* should not be difficult, if the practitioner will but remember that a *contracted or contracting uterus* will not bleed—hence vaginal bleeding which occurs when the uterus is firmly contracted must come from some cause other than atony and its source should be readily detected by exposure and inspection of the parts. Likewise the treatment in these cases is *simple and direct*, namely, the application of a suture ligature or proper closure with sutures of the cervical, vaginal or perineal wound

(b) Internal traumatic hemorrhage is the term applied to traumatic bleeding in which the blood instead of escaping externally flows into the perivaginal or perivulva tissues producing hematomata. The cause is rupture of a varix in one of the subjacent tissues due to obstruction to the venous return by the firmly wedged head—fortunately, it is of very rare occurrence, though the incidence of hematoma of the vulva is such as to fall within the experience of most obstetricians

Hematoma of the Vulva The tumor appears suddenly and is accompanied by severe local pain in one or the other labia. It is globular in shape, elastic in consistency, purple in color, exquisitely tender to touch and gradually increases in size, while ecchymosis is observed in the adjacent tissues

Should the bleeding occur beneath the vaginal wall in the loose cellular tissue of the perirectal space, the pain in the region of the rectum is intense. Some of these internal hemorrhages occur beneath the peritoneum where they may be recognized as a sensitive tumor depressing the Douglas sac and filling one or both of the lateral vaginal fornices. Hematomata may terminate

(1) In rupture with external hemorrhage and death or the bleeding may be controlled and the patient react from her shock

(2) Or it may become a dissecting hematoma extending beneath the peritoneum reaching the perineal space or dissect its way downward into the perineum.

(3) Or the tumor may absorb

(4) Or it may become infected and suppurate

Treatment The treatment is usually expectant unless the tumor mass becomes infected when incision and drainage is desirable

Atonic Hemorrhage Atonic hemorrhage as the name implies is the result of failure of the uterine muscle to contract and the bleeding occurs from the unclamped sinuses in the placental site

When one realizes how separation of the placenta takes place and that only by contraction and retraction of the uterus do the vessels become closed by compression and kinking, it is

not difficult to appreciate why the uterus bleeds. Normally the healthy woman is fortified against the inevitable blood loss of the third stage of labor by the increase in the total amount of blood, the greater amount of contained fibrin and a leucocytosis

Hemorrhage which occurs during the detachment and expulsion of the placenta is normally checked by the united action of three factors, namely

- (1) Uterine contraction
- (2) Uterine retraction
- (3) The formation of thrombi in the mouths of the vessels

Atonic hemorrhage is to a greater or less degree a preventable accident which has many predisposing causes, all of which are more or less controllable in the hands of a competent attendant. While faulty management of the third stage is the most common etiological factor, prolonged labor with *physical exhaustion* or the *prolonged use of anaesthesia* in the second stage are also contributing factors. Furthermore, it is admitted that the *generally weak blond or red-headed women* who have slow labors, tend to lose more blood in the third stage than their darker sisters. In addition, *over-distension of the uterus by twins or hydramnios*, the *presence of tumors, disease in the uterine wall*, or the *too rapid emptying of the uterus*—as in precipitate labor or manual extraction, have a contributing effect

The physiology of the third stage theoretically prevents bleeding by contraction and retraction of the uterine muscle. The steps which take place successively in this stage are

- (1) The separation of the placenta by the formation of a retro-placental blood clot
- (2) Expulsion of the placenta by uterine contractions
- (3) And contraction and retraction of the uterus

The uterine sinuses lying as they do between the muscle lamellae and muscular bundles which when the uterus contracts are crowded together and overslide one another, *bend, twist and compress* the uterine sinuses and thus arrest the current of blood flowing through them. Even the uterine arteries at the side of the uterus become more tortuous and their lumen is decreased as the uterus retracts. All of this takes *time and pain, and cannot be hurried except with danger to the patient*

Could we but teach the practitioner that the management of the third stage was along the physiological lines and that these physiological processes cannot be interfered with, few women would lose any considerable amount of blood

Another practical observation which has a direct bearing on the production of uterine atony, is the practice of beginning the use of anaesthesia

claims that they do not, while a great many other observers, particularly the school of Steinach are perfectly convinced that they do

However, it must be admitted that there is a vast difference between the temporary increase of vigor and sexual activity that follows an enhancement of this endocrine activity and true rejuvenation

Altogether, I believe that the methods of vas deferens ligation and irradiation of the ovary, although it certainly greatly improves the vitality of the subject and helps in bringing about a better endocrine balance, should be considered under the heading of invigoration rather than that of rejuvenation

We must also keep in mind that indiscriminate temporary invigoration may have serious dangers connected with it unless a thorough clinical survey is made first to determine whether the increased pace of existence will not throw too great a strain on certain vital organs. When one applies for rejuvenation he is usually at an age when the heart, kidneys, arteries, etc., are more or less damaged and although these may be perfectly adequate for the activity that the individual had been used to, they might become seriously injured if a decidedly greater strain is thrown upon them. Consequently, in such a case, unless one proceeds very carefully, a shortening of life instead of a lengthening would result

It is hoped, then, that in future discussions on the subject of rejuvenation the meaning of this term will first be clearly defined. Then, much of the confusion which has clouded the subject will be avoided

SUMMARY AND CONCLUSIONS

I Much of the confusion that surrounds the subject of rejuvenation is due to the fact that the term is not clearly defined. It may be considered from four different angles, namely

- (1) Rejuvenation of the external appearance,
- (2) Restoration of diseased organs,

- (3) Mental rejuvenation,
- (4) Cellular rejuvenation

II The truest example of rejuvenation furnished by nature is the life cycle of the paramoecium. This unicellular animal procreates for from five to twenty generations by simple fission. Then copulation with another organism is required, otherwise it will die. The copulation has a true rejuvenating influence

III The term rejuvenation should be limited to a cellular return to youth, i. e., the cells should be so changed as to be in a condition in which they were when they were younger. Only when the cells of the body themselves are restored to youth can the term be applied properly

IV Attempts to restore youth by means of ligation or section of the vas deferens or exposure of the ovaries to X-rays or electric currents are not methods of true rejuvenation. Here, as well as in the case of the first three methods of so-called rejuvenation described, the term "Invigoration" should be used

POST-PARTUM HEMORRHAGE*

By JOHN OSBORN POLAK, M.D., BROOKLYN, N. Y.

THERE is no obstetric emergency that so seriously jeopardizes the patients' life, that calls for such sure and prompt treatment for its relief, and in which all of the courage, resource and skill of the obstetrician is so suddenly put to the test as in a severe case of post-partum hemorrhage—yet, in the opinion of many obstetricians this is a wholly preventable accident. To this teaching, however, I do not fully subscribe, for post-partum hemorrhage does and

always will occur in the practice of midwifery as long as women bear children

Post-partum bleeding has two general sources of origin.

- (1) From birth traumatism
- (2) From uterine atony

Traumatic hemorrhage may be the result of either external or internal trauma

(a) Of the external causes the most common are lacerations occurring about the clitoris, bulbi, perineum and vulva, while those of internal

* Read at the Annual Meeting of the Medical Society of the State of New York, at New York, March 31, 1926

the sinuses—if left in situ for too long a time the uterine muscle tires and good retraction is not obtained

In closing we will call attention first to the fact that sometimes post-partum bleeding is an unavoidable accident, that the cause is always due to traumatism or in the placental site. Injuries

should be sutured—while in the atonic type the uterus should be encouraged to contract by drugs, manipulation and pack, and, finally, that bleeding predisposes to more bleeding, hence active treatment should be begun at once and our measures should be prompt and effective

DIAGNOSIS OF ACUTE PERFORATION OF PEPTIC ULCER*

By CHARLES GORDON HEYD, M.D., NEW YORK

IT is a matter of common knowledge that acute gastro-duodenal perforations are sometimes mistaken for acute perforative appendicitis. The anatomical conformation of the pylorus, duodenum and transverse colon permits the seepage from a perforation in the neighborhood of the pylorus to flow to the right above the transverse colon and then to gravitate downward along the outer side of the ascending colon, and manifest itself, after a few hours, by an inflammatory accumulation in the right iliac fossa. Upon the assumption that it is a case of acute appendicitis, appendectomy is performed, and the real pathological process is unrecognized.

Perforation is the most serious and lethal complication that may occur in the biological history of peptic ulcer. It is always an indication for surgical intervention and imperatively demands immediate diagnosis. Perforation may occur in any type of ulcer—acute or chronic, at any age, at any time, with or without previous symptoms, with or without premonitory signs. Aside from the isolated and relatively infrequent cases where perforation takes place without any previous dyspepsia or gastric disturbance, it occurs as an end-result of chronic peptic ulcer, and while the perforation is acute the ulcer has been present for a variable period of time.

Furthermore, it is to be noted that in the majority of cases where perforation occurs there has been an increased activity both in the pathology of the ulcer and in an exacerbation of the symptoms previous to the moment of perforation. In an ulcer that is about to perforate there are signs of the impending disaster. The patient who has heretofore had a periodic pain, occurring in more or less definite cycles, finds that the pain is becoming constant in character, steady, localized and is not benefited by measures or medicaments that have heretofore availed. The interpretation to be made of this change from a periodic gastric pain to a constant pain is that the peritoneum is becoming inflamed by exudation and that the ulcer is potentially perforating. There is some slight difference in symptomatology depending upon whether the

perforation is gastric or duodenal. The more bulky and less sterile gastric extravasations are in contrast with the greater fluidity of the duodenal contents, and although they modify they do not change the essential features of the symptomatology.

Perforation is essentially an accident in the clinical course of a peptic ulcer, and like all accidents, occurs with dramatic suddenness. The initial symptoms of perforation, and those upon which the diagnosis should be made, are due to the actual mechanical perforation and the chemical assault upon the unguarded peritoneum by the extravasation of gastric or duodenal contents. To wait for the symptoms of the subsequent bacterial peritonitis in order to make a diagnosis is to delay until the mortuary rather than the operating amphitheatre receives the patient.

In abdominal diagnosis it is essential to distinguish the two types of pain that are exhibited most frequently in gastro-intestinal pathology. The first type is that of "colic" and the pain of colic is intense, sudden, acute, but always intermittent, with intervals of complete relief from suffering. It is ordinarily the result of an irritative and functional lesion and is due to hyperactivity of non-striated muscle fibers with spasm. The second type is acute, sudden, intense and always constant, with no intervals of relief. This type is due to actual inflammation of the peritoneum and is the result of perforation and exudation. In the beginning this latter type of pain is localized to the area of exudation, later it becomes more general and extensive. It is always associated with a fixed, tense, immobile body posture in contrast to the restlessness and movement in "colic." In these outstanding points of pain differentiation, we have the key to the diagnosis of acute perforation of the gastro-intestinal tract. In perforation of a peptic ulcer pain is the outstanding symptom, abdominal rigidity the most distinctive physical sign and immobility of body posture the most noticeable feature. Time does not permit nor is the available laboratory data of any noteworthy importance in arriving at the diagnosis in the early stages.

*Read before the Medical Society of the County of New York Monday October 25th 1926

too early in the second stage and thus getting the cumulative effects of the anaesthetic on the contractility of the uterine muscle. This is seen particularly in those clinics where operative delivery in the second stage of labor is the rule, and the patient who has been anaesthetized to a surgical degree, is delivered by forceps or version and not allowed to come out of her anaesthetic, and spontaneously expell the placenta before the repair of her birth injuries is begun. Such practice not infrequently results in atony and bleeding.

Prolonged labor in a patient who has not had sufficient rest is another cause for uterine relaxation, as is also the presence of tumor masses in the uterine wall.

In an experience covering a number of years in which all methods of placental stage management have been employed, and the results of these carefully checked by an accurate measurement of the blood loss—we have come to the conclusion that the smallest blood loss will result in those cases in which after the delivery of the child, the cord is clamped close to the vulva, and no uterine manipulation *whatsoever* is employed to express the placenta, until the signs of placental separation appear. These signs are classical, namely

- (1) Descent of the cord
- (2) The appearance of vaginal bleeding
- (3) The rise of the fundus—and the change in the shape of the uterine body

Not until these evidences of separation occur should any expression be made—and, coincident with this expression, an ampule of pituitary extract is given hypodermatically. A routine such as this followed in several thousand cases has resulted in an average blood loss of less than 200 cc.

The so-called Duncan separation or Duncan mechanism is, in our opinion, the result of a low implantation of the placenta. Over-activity on the part of the attendant. Even a low placenta will normally separate by a Schultze mechanism if the obstetrician will but keep his *mind on the steps of the physiological process and his hands off the uterus*.

Bleeding during the third stage—not of traumatic origin must naturally be grouped into bleeding which occurs *before the placenta is delivered* and hemorrhage *following its delivery*. Therefore in the treatment of bleeding from atony a sharp distinction must be made between the bleeding which occurs before the placenta is delivered and that which continues after its expulsion from a relaxed uterus.

In the former, the placenta must be immediately expelled or removed before other remedial measures for the control of hemorrhage are instituted. This may be done by Crede at the acme of the contraction, or by manual extrac-

tion. *One point that must be stressed is*, that the larger the quantity of blood loss the greater is the tendency toward subsequent atony. Furthermore, a slow but long continued bleeding is more often fatal than a sudden loss checked and the shock combated. Therefore, *it should be an axiom that post-partum bleeding, however slight, should be promptly controlled*.

Bleeding from the placental site is naturally associated with a relaxed uterus, consequently the effort of the obstetrician must be directed toward securing contraction and maintaining uterine retraction. This is done by three procedures

- (1) Drugs
- (2) Manipulation
- (3) The uterine and vaginal tamponade

The historical methods which include the use of styptics, faradism, ice, intrauterine douche, etc., have gone out of vogue and properly so—as have abdominal compression by various mechanical devices and the use of the Mombert belt.

Immediately on the appearance of hemorrhage, after the placenta has been delivered, the woman should be given a hypodermic of an ampule of pituitrin. This should be supplemented by the intramuscular use of Ergone, Gynogen or Ergotol. These drugs act as prompt oxytocics. Coincident with this hypodermic medication the uterus is raised out of the pelvis by spanning the lower segment with the thumb and forefinger and forcibly compressing it against the bifurcation of the aorta as it crosses the sacral promontory, while the other hand on the fundus rubs the organ into contraction. Absolute control of the situation may be had by this maneuver—if the compression is carried on long enough, say, one or two minutes by the clock, for the uterus will contract, clotting occur and the bleeding cease. Crowding the uterus down into the pelvis and constantly expressing clots always increases the amount of blood loss. It is far better should stimulation fail to cause contraction, for the obstetrician to place his gloved hand in the uterine cavity and leave it there as a tampon until contraction occurs.

By following the above routine it is more than five years since we have had to pack the uterus for hemorrhage. When pituitrin, ergot and manipulation by the above technique fails to control the bleeding, the uterus, cervix and vagina should be firmly packed with sterile gauze, which will always arrest the hemorrhage—unless the woman has lost so much blood that contraction and retraction cannot occur.

One point regarding the intrauterine pack should be stressed, namely that when contraction and retraction have been obtained, the pack should be gradually withdrawn this allows the uterus to clamp down upon it and so compress

abdomen than one would be warranted in ascribing to an attack of appendicitis. In addition, physical examination will demonstrate that the area of maximum rigidity is in the epigastrium rather than in the right lower quadrant. The sequence of events in perforation point to a primary upper abdominal lesion with secondary or descending abdominal involvement rather than the ascending peritoneal involvement of an acute appendicitis.

Acute cholecystitis or cholelithiasis should offer little difficulty in diagnosis. Gall bladder disturbance is preeminently a disease of women. The history is all-important as there has probably been previous attacks, and a long history of "gaseous" indigestion. Gangrene and perforation of the gall bladder is fortunately very rare. Here again a history of previous attacks of biliary colic is all-important as well as the sex predilection. Furthermore, gall bladder perforation tends to local exudation and local peritonitis with intense localized pain and localized rigidity.

Acute pancreatitis presents the same dramatic suddenness of onset with agonizing pain as perforation. The condition is, as a rule, found only in florid, thick-set males and very rarely in fe-

males. In pancreatitis the pain, while severe, is transverse, midabdominal, front and back. The pulse is from the beginning bad. The peritoneal reaction and rigidity are localized and epigastric. The facies is different with its lividity, and the breathing while restrained is without catch. The vomiting is early, continuous, persistent, and suggests high intestinal obstruction. Acute intestinal obstruction seldom presents the dramatic characteristics of acute perforation. There is the etiological factor for obstruction—hernia, previous laparotomy, etc. The pain of obstruction is colicky, without marked rigidity. Restlessness is always present. Vomiting is continuous, with rapid changes in the quantity and character of the vomitus.

In conclusion, it is evident that the pathological conditions which must be differentiated from acute perforation, whether it is gangrenous gall bladder, perforative appendicitis, acute pancreatitis or acute intestinal obstruction, are by and of themselves conditions which demand immediate operation. The final word is for early diagnosis and early surgery for the conditions under consideration are all surgical and admit of no other therapy.

UNDULANT FEVER

By RUTH GILBERT M.D., and PAUL B. BROOKS, M.D.

From the New York State Department of Health

"UNDULANT fever" is a term of recent development which, as now commonly used, covers two conditions, i.e., the so-called Malta fever, which is incited by *B. melitensis* and is transmitted to human beings through goat's milk, and another condition arising from infection of human beings with *B. abortus*, an organism responsible for contagious abortion, a disease prevailing extensively among dairy cattle. It now appears that undulant fever of bovine origin occurs not infrequently among human beings and that it creates a problem in the sanitary control of milk similar to that relating to tuberculosis.

B. melitensis and *B. abortus* appear to be closely related and can not ordinarily be distinguished from each other in stained specimens. In milk both would be destroyed by pasteurization at 142° F. for 30 minutes.

Clinically undulant fever may resemble typhoid fever, miliary tuberculosis, malaria or endocarditis, the fever being protracted and "undulating" between normal and 102 to 105 degrees. The spleen is usually enlarged and the lymphocyte count increased, while the number of polymorphleucocytes is not above normal. The infection has a tendency to localize, as in the joints or endocardium. The diagnosis is made in man

through blood cultures, serological tests and animal inoculation.

On November 12, Dr. C. M. Carpenter of Cornell University, at a meeting of the state association of public health laboratories, read a paper prepared by Dr. V. A. Moore, dean of the veterinary college, on "*B. abortus* in Cattle and Man." They have observed several previously undiagnosed cases of this infection in man and others have reported finding this organism in cases of human abortion. In cows, according to these observers, the infection is primarily one of the placenta. The organisms appear in the milk of about 60% of infected cows, while about 30% of the herds examined at Cornell were found to be infected. Passage of the bovine organism through human beings appears to "step-up" its virulence. Cows infected with human strains abort usually within 20 days, while abortion following bovine infection ordinarily does not occur under 6 weeks.

The existence of undulant fever should be suspected in all cases of prolonged febrile reaction in which diagnosis is not clear. Blood—about 10 cc.—should be collected in sterile tubes and a similar amount collected in Keidel blood culture outfits, these specimens being sent to the laboratory immediately for examination.

The pain of perforation is equaled by few and excelled by no other abdominal condition. The onset is sudden, like a bolt of lightning, constant after its appearance, agonizing, unbearable, without any intermission or free intervals as in colic. The pain is made manifestly worse by the slightest movement, and as a result the patient remains in a fixed, tense, immobile posture, usually on his back, with knees flexed. There is not only a disinclination to move but a fear of changing his posture so greatly does bodily movement aggravate the pain. In the beginning the pain is invariably upper abdominal, but rapidly spreads over the entire abdomen. There is a generalized abdominal tenderness which is present almost simultaneously with the onset of pain. The abdomen is rigid to a degree unequaled by any other abdominal condition. The muscles are board-like and retracted. The rigidity is complete and absolute, and does not lessen or abate until death is imminent. The intenseness of the abdominal rigidity is uninfluenced by the will or relaxation upon the part of the patient. With the progressive development of peritonitis, there will be intestinal distention and a lessening of the abdominal retraction, but no relaxation in the intense rigidity. In the beginning the rigidity may vary in some degree in different portions of the abdomen. The most exalted sensibility of the peritoneum is in the neighborhood of the foramen of Winslow, and hence the greatest pain and tenderness are exhibited beneath the upper right rectus muscle. Gentle palpation usually reveals that the greatest degree of rigidity is also in the same area. Percussion of even the lightest kind is painful and resented.

The diaphragm is an abdominal muscle and is held in spastic rigidity. The respirations therefore, are entirely thoracic, of the superior costal type, ending in an expiratory "catch," usually accompanied by an exclamation or groan. The face is pale, alert, anxious, with "beads of sweat" on the forehead. Contrary to the usual conception there is little, if any, shock in the early stages. The reaction of different people to agonizing pain is varied, and while shock may occasionally be observed, its presence or absence is a sign that is not noteworthy and of little diagnostic import. The pulse is hardly accelerated in the first few hours of perforation. The temperature is likewise normal or very slightly elevated. When peritonitis begins to dominate the clinical picture there is an uninterrupted acceleration in pulse rate, with a proportional depreciation in quality and volume. Each succeeding hour the pulse becomes progressively worse. Nausea and vomiting are so frequently associated with any disturbance of function in the gastrointestinal tract that they have no place as diagnostic criteria in the diagnosis of perforating ulcer. Vomiting, when it occurs, is more prominent in duodenal perforation than in gastric,

for in the presence of a perforating duodenal ulcer the stomach is intact and the peritoneal reflex of vomiting will empty the gastric contents, whereas in the perforation of the stomach it will be much easier for the gastric material to escape into the peritoneal cavity than up through the cardia and esophagus.

The obliteration of liver dullness is an inconstant and late sign, for a distention—intra-peritoneal or intestinal—which will obliterate liver dullness marks a stage of generalized peritonitis. In the early hours there is a moderate leucocytosis and polynuclear count, 16,000 to 18,000 leucocytes, with polynuclear percentage of 80 to 85. These should not be taken either for or against the diagnosis except that the presence of a leucocytosis and an increased polynuclear count would eliminate the anginas and the abdominal crises of tabes.

The differential diagnosis will embrace an elimination of the various forms of angina, acute thoracic disease, cholelithiasis, cholecystitis, acute hemorrhagic pancreatitis, acute intestinal obstruction, acute perforating appendicitis and possibly ectopic gestation. The onset of an angina, is, as a rule, sudden, with intense pain, and with the same anxious expression that goes with acute gastroduodenal perforation. Nausea and vomiting may or may not be present in either condition, and is of no value for or against the diagnosis. The patient, however, with an acute peptic perforation will remain fixed in one position as movement exalts the intensity of the pain. The patient with an angina, on the contrary, is restless and changes his position from time to time. The distinguishing features of perforation are the intense degree of abdominal rigidity and the fact that the patient maintains a fixed, tense posture. In acute thoracic disease—pleurisy, central pneumonia, basal pneumonia, diaphragmatic pleurisy—the elevation of temperature is important and the rapidity of respiration significant. While the acute perforation has shallow "catchy" respirations they are not, as a rule, markedly increased in frequency, and an outstanding feature in thoracic conditions is the disproportion that exists between pulse and respiration, as opposed to the normal parallelism of pulse and respiration in acute perforating ulcer. Within a few hours after perforation, by reason of seepage into the right lower quadrant, there is exquisite tenderness and pain over the area of the appendix, but in differentiating acute perforated appendicitis one should remember that the initiatory pain of appendicitis is colicky, intense, but with interrupted or clear intervals. The rigidity is not, as a rule, generalized. There is no catch in the breathing. The facies has neither the anxiousness, the pallor, nor the fear that is present in acute perforation. Moreover, the patient will localize the point of maximum pain and tenderness in perforation at a point higher in the

abdomen than one would be warranted in ascribing to an attack of appendicitis. In addition, physical examination will demonstrate that the area of maximum rigidity is in the epigastrium rather than in the right lower quadrant. The sequence of events in perforation point to a primary upper abdominal lesion with secondary or descending abdominal involvement rather than the ascending peritoneal involvement of an acute appendicitis.

Acute cholecystitis or cholelithiasis should offer little difficulty in diagnosis. Gall bladder disturbance is preeminently a disease of women. The history is all-important as there has probably been previous attacks, and a long history of "gaseous" indigestion. Gangrene and perforation of the gall bladder is fortunately very rare. Here again a history of previous attacks of biliary colic is all-important as well as the sex predilection. Furthermore, gall bladder perforation tends to local exudation and local peritonitis with intense localized pain and localized rigidity.

Acute pancreatitis presents the same dramatic suddenness of onset with agonizing pain as perforation. The condition is, as a rule, found only in florid, thick-set males and very rarely in fe-

males. In pancreatitis the pain, while severe, is transverse, midabdominal, front and back. The pulse is from the beginning bad. The peritoneal reaction and rigidity are localized and epigastric. The facies is different with its lividity, and the breathing while restrained is without catch. The vomiting is early, continuous, persistent, and suggests high intestinal obstruction. Acute intestinal obstruction seldom presents the dramatic characteristics of acute perforation. There is the etiological factor for obstruction—hernia, previous laparotomy, etc. The pain of obstruction is colicky, without marked rigidity. Restlessness is always present. Vomiting is continuous, with rapid changes in the quantity and character of the vomitus.

In conclusion, it is evident that the pathological conditions which must be differentiated from acute perforation, whether it is gangrenous gall bladder, perforative appendicitis, acute pancreatitis or acute intestinal obstruction, are by and of themselves conditions which demand immediate operation. The final word is for early diagnosis and early surgery for the conditions under consideration are all surgical and admit of no other therapy.

UNDULANT FEVER

By RUTH GILBERT M D, and PAUL B BROOKS, M D

From the New York State Department of Health

"UNDULANT fever" is a term of recent development which, as now commonly used, covers two conditions, i.e., the so-called Malta fever, which is incited by *B. melitensis* and is transmitted to human beings through goat's milk, and another condition arising from infection of human beings with *B. abortus*, an organism responsible for contagious abortion, a disease prevailing extensively among dairy cattle. It now appears that undulant fever of bovine origin occurs not infrequently among human beings and that it creates a problem in the sanitary control of milk similar to that relating to tuberculosis.

B. melitensis and *B. abortus* appear to be closely related and can not ordinarily be distinguished from each other in stained specimens. In milk both would be destroyed by pasteurization at 142° F for 30 minutes.

Clinically undulant fever may resemble typhoid fever, miliary tuberculosis, malaria or endocarditis, the fever being protracted and "undulating" between normal and 102 to 105 degrees. The spleen is usually enlarged and the lymphocyte count increased, while the number of polymorphous leucocytes is not above normal. The infection has a tendency to localize, as in the joints or endocardium. The diagnosis is made in man

through blood cultures, serological tests and animal inoculation.

On November 12, Dr. C. M. Carpenter of Cornell University, at a meeting of the state association of public health laboratories, read a paper prepared by Dr. V. A. Moore, dean of the veterinary college, on "*B. abortus* in Cattle and Man." They have observed several previously undiagnosed cases of this infection in man and others have reported finding this organism in cases of human abortion. In cows, according to these observers, the infection is primarily one of the placenta. The organisms appear in the milk of about 60% of infected cows, while about 30% of the herds examined at Cornell were found to be infected. Passage of the bovine organism through human beings appears to "step-up" its virulence. Cows infected with human strains abort usually within 20 days, while abortion following bovine infection ordinarily does not occur under 6 weeks.

The existence of undulant fever should be suspected in all cases of prolonged febrile reaction in which diagnosis is not clear. Blood—about 10 cc—should be collected in sterile tubes and a similar amount collected in Kerdel blood culture outfits, these specimens being sent to the laboratory immediately for examination.

THE DINNER TO DR. DOWNING

The significance of the Medical Practice Act is becoming apparent with increasing clearness with the passing days. Six months of the application of the new law have demonstrated its efficiency and provided a background of experience which justified the recent dinner in commemoration of the passage of the act.

The dinner was a testimonial to Dr. Augustus S. Downing, for he was the outstanding leader in a movement among physicians and the people to secure the highest standards of honesty and

scientific knowledge in the practice of the healing art. The passage of the act involved a contest between those persons who would gamble on a quick recovery from pain, and those who are willing to achieve health and vigor by the industrious application of the principles of physiology and hygiene. Some will continue to speculate in health, but the untrained healers will no longer be permitted to hold forth alluring promises of cures when they know little about physiology and nothing about pathology.

DR GLENWORTH R BUTLER

Dr Glenworth R Butler of Brooklyn finished his life work on December 6, after long years of active usefulness as a leading writer, teacher, and practitioner of medicine. Dr Butler had a large measure of genial friendliness which made his associates feel that his own phenomenal knowl-

edge and diagnostic acumen was theirs also. To him scientific medicine was a spirit of healing service of which he himself was only the bearer and servant. His associates loved him for the generous modesty which beautified his lofty greatness.

A MINIMAL PROGRAM FOR COUNTY MEDICAL SOCIETIES

The leaders of every county medical society are seeking for an outline of activities which the society can carry out. The thousand and more county societies of the United States have developed their activities in almost every possible way. Some act along original lines, and some are followers of the order of lecture program a century old. Some are purely scientific, and others take on social and civic activities.

It would be illuminating to make a study of what the counties of other states are doing, and to compare their activities with those of New York State. The records are found to a great extent in the Journals of the State Societies, but the Michigan State Medical Society has adopted a minimal program which is suited to conditions in that state. The program has been a slow growth and evolution from small beginnings, and has been clearly stated by Dr F. C. Warnshuis, Secretary of the State Society and Speaker of the House of Delegates of the American Medical Association. He groups the activities in five sections.

The first section sets forth the standards of the scientific meetings and reads as follows:

Section 1 *Scientific*

(a) Ten meetings are to be held during the year. Local speakers are to appear before three meetings with definite planned discussions.

(b) A program of physical examinations shall be instituted in which all physician members shall agree to have a complete physical examination themselves, and each shall agree to secure at least five patients who will agree to have complete physical examinations.

Many county societies of New York State hold monthly meetings. Some hold only one or two, but there has been a growth of interest in the meetings which has been stimulated by the frequent visits of the President of the State Society and the Executive Officer during the past year. These visits have been of essential value not only for the encouragement of the presence of the state officers, but also for the opportunities which they have afforded the several societies to learn what the others are doing. The New York societies of counties containing cities of considerable size frequently supply local speakers for their programs, but the members of the local societies

often allow various conditions, including undue modesty, to demand speakers from outside their own circle of members.

Some societies of New York State have adopted the program that all their members shall undergo a physical examination, but Michigan seems to be ahead of New York in expecting that every member shall secure at least five patients who shall consent to be examined.

The second section refers to social activities and reads:

Section 2 *Social and Informal Activities*

Each society is to have at least three dinner meetings. The speakers for these meetings shall be public speakers, educators, financiers, but not medical men. At least one picnic shall be held. At least one social evening, in cooperation with members of closely related organizations, shall be arranged.

The extent of this requirement is not exactly clear. Three dinner meetings, one picnic, and one social evening, make five meetings in addition to the ten scientific meetings of the society, or fifteen meetings in all in the course of the year. Probably no society in New York approaches this standard.

Section three relates to scientific teams and is as follows:

Section 3 *Scientific Teams*

Each society shall have a group of two or three members who will prepare a program and give it on request before at least three other societies.

This standard assumes a degree of originality beyond that of the average county society of New York State. It is an excellent standard and worthy of adoption.

Section four relates to lectures given to lay organizations by local physicians and reads as follows:

Section 4 *Public Health Information and Education*

Each society shall plan to have at least one Public Health lecture group which shall give at least five lectures in cities and communities outside of their resident communities or cities. Adjoining counties are to be included. Each society shall cooperate and assist other organizations so that the following public lectures may be held (Cooperation shall be established with the Ex-

tension Department of the University of Michigan, and the Joint Committee on Public Health)
 1 lecture for each High School
 1 lecture for each Parent-Teacher Association
 1 lecture for each Luncheon Club
 1 lecture for each Woman's Club
 1 lecture for each Association of Commerce

While the physicians of New York generally dislike to "write compositions," still more do they shrink from public speaking, especially if they have to travel to another community. Still, the ideal is laudable and worthy of consideration.

Section five relates to the modern movement to treat the accounts of meetings as news and reads as follows:

Section 5 *Publicity*

Each meeting, scientific or public, shall be reported to the local newspapers in such form that at least one important point of value can be read by the reader.

The Secretary shall report each month to the State Medical Society the complete record of all activities and accomplishments.

This standard has frequently been advocated in

THE NEW YORK STATE JOURNAL OF MEDICINE, and some societies have adopted it. The newspapers are eager to get the items. The field is ready, and it only remains for the local societies to occupy it. There has been a healthy increase in the number of secretaries who report their meetings to the State Journal.

New York seems to excel in its program for bringing graduate education within reach of the members of county societies. The Committee on Public Health and Education has demonstrated that the members of County Societies generally are desirous of studying and keeping themselves abreast of the times.

New York also excels in the practice of civic medicine by county societies. An increasing number are taking the lead in the support of civic projects of a medical nature. It is doubtful that any other state can equal the record of the county societies of New York State in its campaign for anti-diphtheria immunizations.

A consideration of minimal standards of action has the great value of setting forth definite programs from which a choice may be made by any county society.

LOOKING BACKWARD

This Journal Twenty Years Ago

Twenty years ago the words "indigestion" and "dyspepsia" stood for what were supposed to be disease entities whose seat was the stomach. But already the surgeons and gastroenterologists had recognized a long list of pathological conditions which gave rise to the feelings on which a diagnosis of indigestion and dyspepsia was based. It was even suggested that indigestion and dyspepsia were symptoms, and by themselves were of comparatively little importance.

This Journal for December 1906 contains two articles which deal with indigestion. The first is on "The Surgical Treatment of Indigestion" by Dr. E. S. McSweeney, in which the author says, "Removal of the primary cause at a given point means relief for all. This eliminates the functional or idiopathic indigestion where the individual affected is told that he has indigestion, but no one knows where, or what, or why."

This expresses the modern view, that a diagnosis of indigestion or dyspepsia is almost as inadequate as that of catarrh.

The December 1906 issue of this Journal also contains an editorial on Dyspepsia which was evidently inspired by the article of Dr. McSweeney and which reads as follows:

"DYSPEPSIA.—There are many terms in medicine which have been used to designate a disease and which better knowledge has shown are at the most simply groups of symptoms de-

pending upon several different conditions or diseases. The development of medical knowledge upon a pathological basis is eliminating these terms from the catalog of disease entities. Dyspepsia is one of the terms belonging to this confused nomenclature, and in text-books which can not be called old we find it described and treated as a disease. However, it is destined to go the way of jaundice and rheumatism and linger in medicine as an old word applying to a large number of symptoms arising from many different conditions of disease.

"Recent authors have described it as, 'any disturbance in the digestive functions.' This definition is certainly broad enough to comprehend all that the word might imply. When we think of digestion as being made up of two processes, one a chemical process going on in the cardiac end of the stomach, and the other a mechanical process going on in the pyloric end, it seems very convenient to designate as dyspepsia the symptoms arising from disturbance of either of these processes. But the conditions which may give rise to such disturbances are so variant that to include their manifestations under a single head is dangerous to the interests of therapeutics. If the treatment of a disease varies from the administration of bicarbonate of soda to gastrectomy, it is probable that it is not a disease entity."

MEDICAL PROGRESS

Applications of Besredka Vaccines in Local Inflammations Including Chronic Nasal Sinus Affection—E Nikolaeva of the Metchnikoff Institute at Orenbourg, reports in the *Annales de l'Institut Pasteur*, October, 1926, twenty cases of the application of Besredka vaccines in various acute and chronic local inflammations—furunculosis, anthrax, mammitis, otitis, and keratitis. The cultures were made in bouillon, with or without glucose according to the nature of the microorganism, and were used on the 7th to the 10th day, at times much later. They were first heated to 60° C, then filtered through paper, and used purely as dressings. Apparently both stock and autovaccines were used indifferently—the former when there was no opportunity to obtain cultures. In lesions of the skin wound dressings could be applied, but in the external ear instillations, and in stomatitis gargles were substituted. In summing up, the author commends especially the results obtained in furuncle in any stage. In superficial mastitis results were satisfactory but not in deep cases where incision was found necessary. In stomatitis autovaccines gave good results, but in otitis (the external form is referred to) not so good because of mixed infection. In some of the cases treated the rapidity and specific quality of the cure bordered on the marvellous. The keratitis referred to seems to have been an accidental complication of trachoma which responded to the instillation of a culture made from streptococci found in the mucosa of the conjunctival sac. In furuncle, carbuncle, and whitlow the vaccine appeared to reinforce the natural defence, aborting very early cases, promoting early escape of pus, and favoring cicatrization in later stages.

In an article published in the *Journal of the American Medical Association*, May, 1925, Harold Hays reported eminently satisfactory results obtained by vaccines locally applied in the treatment of various nose, throat and ear conditions. He now reports in the *Laryngoscope*, November, 1926, xxvi 11, on a series of over 200 additional cases, chiefly concerning the value of vaccines applied locally in subacute and chronic sinus infections. It is very rarely in these conditions that one sinus alone is involved. The chief value of the vaccine, in the writer's opinion, is due to the fact that, instead of isolating and regrowing the predominating bacteria, which may or may not be at fault, use is made of all the bacteria obtained from the diseased part with any or all of the eliminative properties of these organisms, since the latter may have a very important part in the disease

process. The plan of treatment consists in a thorough examination, including trans-illumination and a roentgenological examination. If pus is present a culture should be taken on a sterile swab and immersed in sugar bouillon at once, since delay may mean an unsatisfactory vaccine. The nose is then thoroughly cleansed, using the suction apparatus, and three successive bottles of washings are kept for comparison. The vaccine is usually applied in eight treatments at intervals of three or four days, and in the interim the patient uses the vaccine twice a day in the form of a spray. Before applying the broth vaccine the mucous membranes are only slightly shrunk with cocaine and adrenalin, as too much shrinking interferes with the absorption of the vaccine. The broth vaccine is applied on long strips of cotton or one-half inch gauze, packed into the nares and allowed to remain for 20 minutes to a half an hour. The nose is then sprayed with an antiseptic oil. Usually at about the fourth week a decided improvement is noted. A case is cited in which, following the removal of a carcinoma of the antrum, sinus infection persisted and a fistula formed. After the application of the vaccine to the antrum the entire condition cleared up. The results in this case suggest the possibility that various bacteria may play a part in the spread of cancer, and the writer suggests that the vaccine may possibly have a specific effect in certain cases of malignant growth.

Spontaneous Disappearance of Cancer—Otto Strauss divides this subject into five, as follows: 1 Disappearance of a primary cancer or of a recurrent one. 2 Disappearance after a palliative procedure. 3 Disappearance after an incomplete operation. 4 Disappearance as the result of a febrile process. 5 Spontaneous disappearance of sarcoma. It is contrary to all logic for a malignant growth ever to heal spontaneously yet we must bear in mind many recorded cases. We must avoid all confusion of terms. Spontaneous disappearance can only mean that the growth vanishes utterly without trace. An arrest, a diminution of size, a sloughing out, these are not the same. The author cites many cases reported by contemporary observers which virtually may be called cases of spontaneous recovery. They may be spoken of as clinical cures perhaps, but are not completely documented. In some the observation period was brief, in others there were residues of the growth still present. There is however, a lack of autopsy control and from the

nature of things of microscopic control as well. The locality is of significance, for in cases of apparent cure of cancer of the stomach following gastroenterostomy and of cancer of the rectum after colostomy the evidence must at times be purely negative. After analysis of the type of these cases the author expresses his belief that in spontaneous disappearance we are dealing really with peculiarities of course and not with any curative process in which the body defences prevail over the malignancy. Strictly construed he finds no case which can justly be called of this type. To speak of an ideal defence in such cases is only to deceive ourselves. Of the 52 cases analyzed by the author not one is above criticism. At most there is only partial involution. By contrast there have been perfectly documented cases of spontaneous recovery of sarcoma, although the author cites only two, seen respectively by Muller of Rostock and F. König of Göttingen.—*Deutsche medizinische Wochenschrift*, October 22, 1926.

Periodic Variability of Some Forms of Arterial Hypertension—Louis H. Sigler says it is well known that posture, activity, digestive processes, and nervous excitement are determining factors in increasing or decreasing the blood pressure readings of a given individual at any given time, but little study has been made of the cases showing periodic variabilities bordering on the normal or even subnormal, only to return again to the original reading. He reports five cases in the *American Journal of the Medical Sciences* for October, 1926, cxvii, 4, in which such changes occurred without any recognizable cause. These variations lasted for periods of hours or days, and were apparently unassociated with any other physical or mental disturbances than those experienced by the individual during the hypertensive period. Pathological changes in the circulatory and renal structures, as shown by clinical manifestations, could not account for these variations. It would seem as though they were dependent mainly upon the vegetative nervous system, and may be analogous to the psyche in insanity cases with exacerbations and remissions, independent of the general constitutional state. This would mean that, for hypertension to occur, there need not necessarily be a diseased condition of any other system, but there must be some structural or functional abnormality in the vegetative nervous system making it susceptible to stimuli—toxic, infectious, neurogenic, or metabolic—that under ordinary circumstances are ineffective. No attempt has been made to determine a possible anatomical alteration in the vegetative nervous system in hypertension. The fact that these falls in blood pressure oc-

curred without and with treatment seems to discredit many of the prevailing "cures" for hypertension.

A Consideration of Arteriosclerosis of the Cerebral Vessels and the Pathogenesis of Hypertension—Since the classical work of Gull and Sutton, fifty years ago, it has been supposed that there is an intimate relationship between arterial thickening and the anatomical changes which today are recognized as being associated with increased arterial tension. In the study of this relationship much painstaking work has resulted in many hypotheses, most of which have been found inadequate. Thinking it might be possible to explain the more or less chronic states of hypertension upon the basis of localization of vascular changes in the region of the vasomotor center, James Bordley III and B. M. Baker, Jr., (*Bulletin of the Johns Hopkins Hospital*, October, 1926, xxxix, 10) have studied twenty-four brain specimens in cases of generalized arteriosclerosis. These investigations have established a constant relation between structural changes in the arterioles supplying the medulla oblongata and persistent states of arterial hypertension, and suggest that such arterial changes constitute an anatomical basis for the explanation of sustained arterial hypertension. It is highly probable that these changes would tend to diminish the blood supply to the part concerned. With such a diminution, experimental evidence would make it seem a just conclusion that a compensatory elevation in blood pressure would be demanded. This suggests that if the elevation in blood pressure is compensatory in nature, one can do nothing more deleterious than to induce an artificial fall, a fact well recognized by clinicians. The changes which were found in the medulla oblongata were not strictly localized to this area, but seemed to constitute only a part of a process which may, and nearly always does, occur in other organs. The arteriosclerosis is frequently found to be more extreme in the kidneys than in the medulla oblongata. These investigations do not explain all varieties of hypertension. Transient elevations of blood pressure cannot be explained on the basis of what would appear to be permanent vascular lesions. The authors feel, however, that their investigation provides an anatomical explanation, supported by experimental fact, for persistent elevation of the blood pressure.

Nasal Sinusitis as a Cause of Toxemia—Sir William Willcox, writing in *The Practitioner*, September, 1926, cxvii, 3, expresses himself as greatly impressed with the importance of nasal sinusitis as a cause of toxemia and disease of other organs. As dental sepsis

is often latent and can be demonstrated only by roentgenological methods, so in nasal sinusitis the existence of a focus of infection is quite latent in a large number of cases and gives rise to no local symptoms. In cases of systemic disease, which may possibly be due to a local condition, careful search should always be made for any evidence of sinusitis, employing radiography and transillumination. Adequate treatment of nasal sinusitis is imperative, since if it is left untreated the focus of infection will speedily give rise to systemic disease. The management of every case of nasal sinusitis should be based upon the view that one is dealing with a case of toxemia, usually streptococcal, where the focus of infection is in the nasal sinuses. Each case is, therefore, a problem in immunity, and should be treated from this standpoint. In cases in which the toxemia is acute, it is best to delay operation until the acute toxemic symptoms have subsided. In chronic cases not too much in the way of treatment should be done at one time, so that opportunity may be given for recovery from the resulting autoinfection. Where foci of infection exist in other parts, as the tonsils or teeth, an interval of time after the sinus operation should be allowed before proceeding with further surgical measures.

Prognosis and Treatment of Epidemic Encephalitis—Professor Heimicke of Chemnitz sums up an article on this subject, the result of his experience in the new station for encephalitis victims at Chemnitz-Altendorf, which is an annex of the Educational Institute for the Blind and Feeble-Minded. The acute form of the disease, he says, yields to but one remedy—the injection of convalescent serum. This will not only save life but prevent the disastrous chronic stage and sequelæ. The serum should also be tried at later periods after the chronic stage has set in. The author particularizes two syndromes which may follow the outbreak. One he terms the pseudo-neurasthenic stage in which the symptoms of neurasthenia are mimicked closely, as headache, prostration, etc. The other is the pseudo-psychopathic, by which term the author signifies the so-called character and personality changes in both children and adolescents. It is in these two syndromes that the serum may be of benefit and this is also true of symptoms of psychosis. Generally speaking unilateral cases have a better prognosis than bilateral. It is unfortunate, the writer thinks, that the great value of convalescent serum is not well understood, and the serum itself may be difficult to obtain. In its absence the best remedy is sodium salicylate. Others which may be tested are collargol and trypaflavin, although

the author shows no enthusiasm for either—*Muenchener medizinische Wochenschrift*, October 1, 1926.

Physical Build and Type of Psychosis—This subject, which was given a great impetus by Kretschmer's book, continues to claim much space in German psychiatric literature. In the *Archiv f. Psychiatrie* for October 8, 1926 (vol. LXXVIII, No. 3) we find two papers, of which the first, by Georgi and two collaborators, appears to bear out the truth of Kretschmer's claim remarkably, at least for Silesia. The number of insane examined anthropometrically was 104 and two groups were made, of which one was the pyknic or compact and well knit, while the other contained the athletic, asthenic (the authors prefer the term leptosome), dysplastic, and mixtures of the three. Practically none of the manic-depressives was found in the second physical type and few schizophrenics in the first. However this does not exhaust the material, for there were numerous individuals in which the two opposed types were blended, all presenting pyknic traits in some degree. If we call these pyknoids then the latter were found in both manic-depressives and schizophrenics and to about the same extent. The second paper by Professor Weichbrodt was frankly skeptical and he placed the labors of Kretschmer in the same category with the past attempts of Gall, Spurzheim, Lavator, Lombroso, and all who attempt to associate mental and physical traits, including the scientific graphologists. Even if the innovators are partly right, he says, they still do no good and do not represent progress. He concludes with Goethe's advice to scientific men to avoid alike that which is unknowable and that which is not worth the effort.

Idiosyncrasy—The variety and complexity of the problem of idiosyncrasy appear to be yielding slowly to experimentation and W. Jadassohn relates a great number of tests made by himself, beginning with pollen idiosyncrasy and hay fever. A series of 15 hay-fever patients who had never presented urticaria in any form, but who invariably suffered from hay fever during the season, reacted by urticaria to the intradermic test made with the specific pollen. Normal controls subjected to the same test with the antigen failed to react with but three exceptions in which urticaria likewise developed. These three subjects were never troubled with hay fever during the season. Some of the hay-fever subjects when subjected to the action of a local irritant under an impermeable membrane reacted with an eczematous outbreak after 24 hours contact, but double or multiple idiosyncrasy is rare,

nature of things of microscopic control as well. The locality is of significance, for in cases of apparent cure of cancer of the stomach following gastroenterostomy and of cancer of the rectum after colostomy the evidence must at times be purely negative. After analysis of the type of these cases the author expresses his belief that in spontaneous disappearance we are dealing really with peculiarities of course and not with any curative process in which the body defences prevail over the malignancy. Strictly construed he finds no case which can justly be called of this type. To speak of an ideal defence in such cases is only to deceive ourselves. Of the 52 cases analyzed by the author not one is above criticism. At most there is only partial involution. By contrast there have been perfectly documented cases of spontaneous recovery of sarcoma, although the author cites only two, seen respectively by Muller of Rostock and F. König of Göttingen.—*Deutsche medizinische Wochenschrift*, October 22, 1926.

Periodic Variability of Some Forms of Arterial Hypertension—Louis H. Sigler says it is well known that posture, activity, digestive processes, and nervous excitement are determining factors in increasing or decreasing the blood pressure readings of a given individual at any given time, but little study has been made of the cases showing periodic variabilities bordering on the normal or even subnormal, only to return again to the original reading. He reports five cases in the *American Journal of the Medical Sciences* for October, 1926, clxxii, 4, in which such changes occurred without any recognizable cause. These variations lasted for periods of hours or days, and were apparently unassociated with any other physical or mental disturbances than those experienced by the individual during the hypertensive period. Pathological changes in the circulatory and renal structures, as shown by clinical manifestations, could not account for these variations. It would seem as though they were dependent mainly upon the vegetative nervous system, and may be analogous to the psyche in insanity cases with exacerbations and remissions, independent of the general constitutional state. This would mean that, for hypertension to occur, there need not necessarily be a diseased condition of any other system, but there must be some structural or functional abnormality in the vegetative nervous system making it susceptible to stimuli—toxic, infectious, neurogenic, or metabolic—that under ordinary circumstances are ineffective. No attempt has been made to determine a possible anatomical alteration in the vegetative nervous system in hypertension. The fact that these falls in blood pressure oc-

curred without and with treatment seems to discredit many of the prevailing "cures" for hypertension.

A Consideration of Arteriosclerosis of the Cerebral Vessels and the Pathogenesis of Hypertension—Since the classical work of Gull and Sutton, fifty years ago, it has been supposed that there is an intimate relationship between arterial thickening and the anatomical changes which today are recognized as being associated with increased arterial tension. In the study of this relationship much painstaking work has resulted in many hypotheses, most of which have been found inadequate. Thinking it might be possible to explain the more or less chronic states of hypertension upon the basis of localization of vascular changes in the region of the vasomotor center, James Bordley III and B. M. Baker, Jr., (*Bulletin of the Johns Hopkins Hospital*, October, 1926, \\\, 10) have studied twenty-four brain specimens in cases of generalized arteriosclerosis. These investigations have established a constant relation between structural changes in the arterioles supplying the medulla oblongata and persistent states of arterial hypertension, and suggest that such arterial changes constitute an anatomical basis for the explanation of sustained arterial hypertension. It is highly probable that these changes would tend to diminish the blood supply to the part concerned. With such a diminution, experimental evidence would make it seem a just conclusion that a compensatory elevation in blood pressure would be demanded. LEGAL

By LLOYD PAUL STRYKER, Esq.
Counsel, Medical Society of the State of New York

CRITICISM OF PHYSICIANS BY PHYSICIANS

There is no profession requiring a higher degree of care, skill or learning or necessitating adherence to a higher standard of honor than that of the practice of medicine. There is no profession that renders a higher service to mankind, there is none that performs more gratuitous service, there is none more indispensable to the human race in peace and in war.

Yet, because of the ignorance of the laity and their inability to appreciate and thoroughly grasp the grave problems confronted by every physician in his contest with disease and death, there is no profession which comes in more frequently for criticism. Nothing could be more unfortunate or deplorable than criticism of the profession, or a given member of it, which has its source in some thoughtless or unfounded remark made by one physician concerning the conduct of another.

"Into whatever houses I enter," wrote Hippocrates in his famous oath, "I will go into them for the benefit of the sick and will abstain from every voluntary act of mischief and corruption," "The principles of fair conduct embodied in this oath four hundred years before the birth of Christ are still recognized as controlling principles for the medical profession. This oath at the present time or a modification of it, is administered to graduates of the majority of the medical colleges of this State.

Amplifying the doctrines of this oath, the *Principles of Professional Conduct* of the Medical Society of the State of New York define in considerable detail the duties of physicians to the profession to the patient and to the public. The various county societies are charged with the duty of carrying out these principles to the best of their ability.

"Everyone on entering the medical profession and thereby becoming entitled to full professional fellowship," declares the first section of these *Principles of Conduct*, "incurs an obligation to guard and uphold its high standard of honor, to conform to the principles of professional conduct and to comport himself as a gentleman."

The third section of these *Principles* declares that "The medical profession exacts from its members the highest type of character and morals, and to attain such a standard is a duty every physician owes alike to the profession and to the public."

Section 11 provides that "In consultations no insincerity, rivalry or envy should be indulged. All due respect should be observed toward the physician in charge of the case and *no statement or remark* should be made which would unjustly impair the confidence reposed in him." And the following section (12) reads "All statements of the case to the patient or his representative should take place in the presence of all the physicians consulting, except as otherwise agreed, no opinions should be delivered which are not the result of concurrence."

Section 24 declares "Diversity of opinion or opposition of interests may sometimes occasion controversy and even contention. Whenever such instances occur and cannot be adjusted, they should be referred for arbitration, preferably to the Board of Censors of the County Society of which such physicians are members."

The first article of the *Constitution* of the Medical Society of the State of New York declares that "The purposes of the Society shall be to federate and bring into one compact organization the medical profession of the State of New York, to promote friendly intercourse among physicians, to guard and foster the material interests of its members, and to protect them against imposition."

These principles, of course, do not mean that it is the duty of a physician in any case to fail in doing all that may be necessary and proper to bring about a good result for his patient, nor do they mean that he should suppress facts as to the commission of a crime. Neither do they mean that the failure of his predecessor in a case to follow the proper practice imposes upon him the duty of continuing the same fault. These principles, however, do mean that unnecessary, and especially unjust, criticism of a brother physician should at all times be avoided.

No doctor possesses perfect skill or perfect knowledge. Every doctor, until the contrary is shown, is entitled to the presumption that he has used his best skill and his best knowledge in order to achieve a good result. In so complicated a subject as medicine it is inevitable that there should be differences of opinion. The judgment of two or more physicians may differ, just as may be the case with other citizens or members of other professions. Honest

usually one who reacts by urticaria fails to develop eczema and vice versa. A patient with celery idiosyncrasy reacted by urticaria but could not be made to develop eczema. In making tests for egg albumin idiosyncrasy it has been shown that the antigen is not the albumin itself for this can be dialyzed out. The author made numerous tests for the presence of antibodies by the method of Prausnitz and Kustner. Symmetrical areas of skin as far apart as possible are treated respectively with some antigen and normal serum. In 24 hours a second test is made, and if urticaria develops in the sensitized area it indicates that a specific antibody has formed in that area. Positive reactions were obtained in all of the members of the group—hay fever, asthma, urticarial dermatoses, and toxicodermatoses—*Klinische Wochenschrift*, Oct 15, 1926.

Traumatic Neurosis—Heidrick of Professor H. Küttner's surgical clinic takes up especially the subject of a post-commotional nervous syndrome following blunt violence to the head, and reviews 14 cases with emphasis on the association of organic lesions. It is known that the neurosis may be purely functional and akin to hysteria and also that with refinements of microscopic technique minute lesions are being found with increasing frequency. In medicolegal practice there is of course no distinction made between functional and structural neuroses. Some of the lesions are fibrous arachnitis, minute meningeal and cerebral hemorrhages, and scars in the glia. Immediately following the violence there is invariably in the author's experience *commotio cerebri*, and as a rule there are at least six months of latency before the appearance of the nervous syndrome. When the symptoms appear they are typical—headache, disinclination for work, vertigo, loss of memory. Objectively the findings are both few and vague even when present. When these patients present themselves in the clinic the pressure of the cerebrospinal fluid is at once taken and is usually found markedly increased. The fluid itself is normal. Encephalograms may show anomalies of the ventricles either primary or after inflation of air. There is a third diagnostic resource, timing the passage of injected phenolphthalein from the spinal canal to the urine. It is believed in a general way that if any of these three tests is positive, and especially if two or more coexist, organic disease is likely to be present, but the author has his doubts as to the wisdom of inflating with air or of injecting test fluids in the canal for it could in theory be possible to add trauma to trauma—*Bruns's Beiträge z klin Chirurgie*, 1926, vol cxxxvii, No 4.

The Disease Picture of Yellow Fever—Professor W. H. Hoffmann of the University of Havana is the legatee of all the documents relative to yellow fever accumulated by the late Dr. Juan Guitéras, who for a quarter century was a student of this affection. These include 107 case histories collected by the deceased in his own practice. The author carefully analyzes these and his summary is as follows: Yellow fever is a form of sepsis of a hemorrhagic type due to the activity of the *Leptospira icteroides*. The toxin formed by this organism attacks especially the parenchymatous organs (liver, kidneys), the myocardium, and blood vessels, producing a severe form of acute degeneration which often leads rapidly to death. The hemorrhages and vomiting of blood are due to degeneration of the vessels. The hemolysis and absorption of hemoglobin are responsible for the jaundice. The presence of the *Leptospira* in the blood causes the formation of powerful antibodies which makes recovery possible in a certain number of cases. Children may have the disease in an extremely mild form and then the diagnosis may be so difficult that in certain cases only the presence of the specific microorganism can clinch it—*Deutsche medizinische Wochenschrift*, Oct 8, 1926.

Cervical Gestation—P. Schneider of Professor Halban's Vienna gynecological clinic has placed on record for the first time a case of undoubted gestation in the cervical canal, a condition said in reference works to be unknown to exist. The ovum was but two months old. The patient, admitted for metrorrhagia, was thought to have an ordinary abortion but after curettage bleeding continued and the ovum covered with chorionic villi was found projecting at the partly dilated os. Further investigation showed that the blood was pouring from a cavity in the left side of the cervix the size of an English walnut, this cavity representing the place of nesting of the ovum and having a wall of paper-like thinness in one place. It was necessary to tampon this cavity. Examination of a portion of the cervix left no possible doubt that there had been an original implantation of the ovum in the cervical canal. Although no other case could be found on record there is an allied condition known as *cervix placenta*, which is also extremely rare. In 1922 Zangemeister and Schilling were able to find but 30 recorded cases, although two years later E. A. Müller who went over the ground with extreme care was able to raise the total to 55, while three others have been reported in the past two years—*Archiv f Gynakologie*, Sept 2, 1926, (vol cxxix, No 2).

found that the median and ulnar nerves had been injured, which caused the contraction and atrophy of the muscles and tendons of the fingers, resulting in a "claw hand" with a permanent loss of about ninety-five per cent of function. The examining physician concluded his report as follows: "There is no doubt in my mind that the patient suffered from a virulent type of infection, as can be noted from the rapidity with which it spread. Furthermore it is apparent that the attending physician was very active in attempting to limit its spread. He was apparently awake to the gravity of the situation by having her admitted to a hospital and administering an anaesthesia each time so that his care would be

thorough. Not infrequently these types of cases require amputation of the extremity."

This action came on the calendar for trial. Plaintiff not being ready to proceed, the complaint was dismissed. The plaintiff then moved to restore the case to the calendar for trial, which motion was granted. When the case again came on the calendar for trial, the plaintiff again was not ready to proceed with the trial of the action and a motion was made on behalf of the defendant to dismiss the complaint for failure of the plaintiff to prosecute it, which motion was granted, finally terminating this action in favor of the defendant after it had been pending for a period of about five years.

MASTOIDITIS FOLLOWING INFLUENZA—COLLECTION OF BILL— COUNTERCLAIM

A physician had attended a patient more or less continuously for a period of about five months. The patient paid part of her bill and refused to pay the balance. After numerous demands the physician caused a suit to be instituted for the collection of his bill. In answer to this suit a counterclaim of alleged malpractice was interposed charging the defendant with negligence and carelessness in his attention, treatment and care of her during her illness. The patient claimed that the injuries she sustained by reason of the physician's negligent treatment were an aggravated catarrhal condition of the right middle ear and defective hearing in said ear, the formation of an abscess in the right ear and a diseased condition of the mastoid and nasal sections and that it was necessary to have an operation performed for the mastoid condition. She sought to recover from the physician for the expenses she claimed to have been put to in the mastoid operation and in the treatment by other physicians and hospital expenses subsequent to her treatment by the plaintiff physician, the amount of which exceeded the balance due the plaintiff for his services.

The plaintiff physician had been called on January 28th to attend the patient, an unmarried woman about forty-seven years of age. On examination he found her suffering from influenza and bronchitis and ordered her transferred to a hospital, where he saw her the following morning. He then properly prescribed for her condition and saw her twice daily until February 27th. On this day she complained of pain in the right

ear. Upon examination he found the tympanum was congested, which condition he watched for two days, when he found the tympanum bulging. This physician, being an internal medicine man, called a nose and throat specialist to attend the ear condition. On February 9th the surgeon, without anaesthesia, incised the tympanum and ordered douching of the ear with hot salines and the spraying of the nose with adrenaline-chloride. This treatment was followed at frequent intervals until February 25th, at which time the ear discharge had subsided. She was again seen in consultation by the ear surgeon, who ordered X-ray. The X-ray disclosed empyema of the mastoid. A smear was then taken of the discharge from the ear. The hospital laboratory reported the presence of diplococcus and streptococcus. On February 28th the ear surgeon, under a general anaesthesia, performed a mastoidectomy. A smear of the pus taken at this time showed the presence of hemolytic streptococcus. Until May 16th the mastoid wound was taken care of and dressed by the plaintiff physician and by the surgeon. On this latter date the wound had healed and needed no further care, at which time she was discharged from the hospital and no further treatment was rendered her by this physician.

When the matter was about to be reached for trial, the same was compromised, the physician accepting a lesser sum in satisfaction of his claim and the counterclaim of alleged malpractice being withdrawn.

errors of judgment may be made by the most learned and the most competent, but such things should not be paraded by other physicians

It would be impossible to give an accurate estimate of the number of malpractice cases which have arisen by reason of some criticism or comment which one doctor made about the conduct of another. We have known of cases in which such comments, oftentimes wholly unjust, have resulted in the creation of an opinion in the mind of the patient or his family that the doctor criticized was at fault.

Physicians who recognize (as all of them

must) that it is their primary duty "to conform to the principles of professional conduct" and to comport themselves as gentlemen—must be aware of their obligation not to indulge in unjust or unfounded criticism. Most of the criticism leveled by one doctor against another arises no doubt from thoughtlessness rather than from malice, and yet the unfortunate results of such criticism may be that a thoroughly competent physician who has used his best judgment and his highest skill, care and learning, may be subjected to the mental suffering and the serious financial hazard of an action for malpractice.

LACERATION OF THUMB FOLLOWED BY INFECTION RESULTING IN LOSS OF FUNCTION OF HAND

In this case the complaint charged a physician with having represented himself to be a competent physician and surgeon and that on the 23rd of December he was employed to heal a cut the patient had sustained to her right hand and properly to care for the same, that through his negligence and carelessness and his failure to use the proper care, medicines and appliances, the wound was not healed but became infected and the patient was caused to suffer great pain and anguish, her hand had become disfigured, diseased and stiffened, the fingers of her hand had become numb, she had lost the sense of feeling and the use of her right hand and arm, that her general health had been impaired and weakened and she was unable to perform her household duties.

On December 21st the plaintiff, while engaged in her household duties, had cut the palm and inner surface of her right hand with a kitchen knife, which she had treated with home remedies. On December 23rd the defendant physician was first called to attend the plaintiff. At that time he found the thumb of the right hand badly infected and swollen. He prescribed wet dressings. On the following day he incised the inside and outside of the thumb, inserting a gauze drain and continued the wet dressings. Thereafter from day to day he attended the plaintiff and properly treated her injury. The infection, however, did not subside but continued to spread over the entire hand and up the arm. On December 29th he had her admitted to a hospital and called a surgeon in consultation and on that day, under an anaesthesia, the incision of the thumb was extended on to the hand forming a semi-circle. On the following day longitudinal incisions were made on the palm and counter-incisions made on the back of the hand and the forearm was also incised as the infection had extended up the arm. The incisions

were kept open with gauze drains and wet dressings were applied. The patient continued to remain at the hospital until January 9th, during which time she was seen daily by the defendant and her injury given the necessary and proper care. On this day she was discharged from the hospital. She continued under the treatment of the defendant at intervals until the end of March, being given massage and other treatment to restore the function of the hand, which had become impaired by reason of the virulency of the infection.

On a physical examination made in the following year, the hand was found to be partly closed and partly open, the fingers stiff except for a small amount of motion in the thumb and little finger, the fingers were purple in appearance and felt cold and looked shriveled. There was a horse-shoe shaped scar on the palmar surface, a linear scar on the dorsal surface and a scar on the forearm. The motion of the wrist was diminished to about one-half of the normal and radial flexion was entirely gone. The function of the thumb was impaired so that the distal phalangeal joint was stiff and partly flexed. The metacarpo-phalangeal joint allowed flexion so that the tip of the thumb could be adducted to the base of the middle finger, abduction and extension were markedly diminished. There was very little holding power by adduction of the thumb. The index finger had no power of function, the same being straight and stiff. There was no function in the middle and ring fingers, they being straight and stiff. There was some movement present in the little finger but functionally of little use. The patient could not pick up anything, but after pushing an object to the end of a table or chair, would grasp it in the web between the thumb and the index finger. Nothing flat could be raised from the floor. There was also a diminution of sensation. The examining physician

found that the median and ulnar nerves had been injured, which caused the contraction and atrophy of the muscles and tendons of the fingers, resulting in a "claw hand" with a permanent loss of about ninety-five per cent of function. The examining physician concluded his report as follows: "There is no doubt in my mind that the patient suffered from a virulent type of infection, as can be noted from the rapidity with which it spread. Furthermore it is apparent that the attending physician was very active in attempting to limit its spread. He was apparently awake to the gravity of the situation by having her admitted to a hospital and administering an anaesthesia each time so that his care would be

thorough. Not infrequently these types of cases require amputation of the extremity."

This action came on the calendar for trial. Plaintiff not being ready to proceed, the complaint was dismissed. The plaintiff then moved to restore the case to the calendar for trial, which motion was granted. When the case again came on the calendar for trial, the plaintiff again was not ready to proceed with the trial of the action and a motion was made on behalf of the defendant to dismiss the complaint for failure of the plaintiff to prosecute it, which motion was granted, finally terminating this action in favor of the defendant after it had been pending for a period of about five years.

MASTOIDITIS FOLLOWING INFLUENZA—COLLECTION OF BILL— COUNTERCLAIM

A physician had attended a patient more or less continuously for a period of about five months. The patient paid part of her bill and refused to pay the balance. After numerous demands the physician caused a suit to be instituted for the collection of his bill. In answer to this suit a counterclaim of alleged malpractice was interposed charging the defendant with negligence and carelessness in his attention, treatment and care of her during her illness. The patient claimed that the injuries she sustained by reason of the physician's negligent treatment were an aggravated catarrhal condition of the right middle ear and defective hearing in said ear, the formation of an abscess in the right ear and a diseased condition of the mastoid and nasal sections and that it was necessary to have an operation performed for the mastoid condition. She sought to recover from the physician for the expenses she claimed to have been put to in the mastoid operation and in the treatment by other physicians and hospital expenses subsequent to her treatment by the plaintiff physician, the amount of which exceeded the balance due the plaintiff for his services.

The plaintiff physician had been called on January 28th to attend the patient, an unmarried woman about forty-seven years of age. On examination he found her suffering from influenza and bronchitis and ordered her transferred to a hospital, where he saw her the following morning. He then properly prescribed for her condition and saw her twice daily until February 27th. On this day she complained of pain in the right

ear. Upon examination he found the tympanum was congested, which condition he watched for two days, when he found the tympanum bulging. This physician, being an internal medicine man, called a nose and throat specialist to attend the ear condition. On February 9th the surgeon, without anaesthesia, incised the tympanum and ordered douching of the ear with hot salines and the spraying of the nose with adrenaline-chloride. This treatment was followed at frequent intervals until February 25th, at which time the ear discharge had subsided. She was again seen in consultation by the ear surgeon, who ordered X-ray. Until May 16th the mastoid wound was taken care of and dressed by the plaintiff physician and by the surgeon. On this latter date the wound had healed and needed no further care, at which time she was discharged from the hospital and no further treatment was rendered her by this physician.

When the matter was about to be reached for trial, the same was compromised, the physician accepting a lesser sum in satisfaction of his claim and the counterclaim of alleged malpractice being withdrawn.

NEWS NOTES

DINNER TO DR AUGUSTUS S DOWNING

The dinner to Dr Augustus S Downing that was announced in the last two issues of the Journal was held on the evening of December 9, 1926, in the Hotel Commodore. The arrangements were in the hands of a Medical Committee of which Dr Orrin S Wightman was Chairman, Dr S Dana Hubbard, Secretary, and Dr James Pedersen, Treasurer, but the participants included representatives of the practice of osteopathy, dentistry, pharmacy, nursing, optometry, veterinary, and podiatry, all of which have been assigned by law to Dr Downing's Division for supervision and regulation. The banquet room was filled to its capacity, 410 being present.

Dr Livingston Farrand, President of Cornell University, presided as toastmaster, and in his opening address he called attention to the special object of the meeting, which was to recognize the progressive work of Dr Downing in gradually raising the standards of professional education over a period of a quarter of a century. Dr Downing has held the position of Director of Professional Education in the New York State Department of Education since the year 1908, and in his position he has had charge of the execution of the laws relating to the professions allied to medicine, including pharmacy, veterinary, dentistry, nursing, optometry, and podiatry, and also certified accountancy, surveying and other professions that require expert knowledge and training. The crowning work of Dr Downing was the passage of the Medical Practice Act last spring, and this has been the immediate occasion for the present memorial dinner. While physicians have taken the lead in the arrangements, members of all the other professions have been included. Moreover the dinner is not merely in celebration of the passage of the medical practice act, but it is in recognition of a series of accomplishments of which the medical practice act was the last.

Dr O S Wightman, chairman of the Committee on Arrangements, read a list of those from whom congratulatory letters and telegrams had been received, including Governor Alfred E Smith, Dr Nicholas Murray Butler, Dr Olin West, and Senator R S Copeland. When Dr Downing saw the list he said "I do not see why they did it!" Dr Wightman commented that this remark was the best possible evidence of the greatness of Dr Downing.

Dr Wendell Phillips, President of the American Medical Association, spoke on the subject "The Application of the Modern Knowledge of Medicine." He called attention to the increasing

demand by industrial plants that physicians should examine their employees, and detect incipient physical defects, for the number of days lost by illness is seven times as great as those by accident.

Dr Phillips referred to the very great value of the old time preceptor who taught his pupils the art of practicing medicine in such a way that the patients were satisfied. They treated the patient rather than the disease.

The suggestion has been made that two types of doctors be recognized, one highly trained scientifically, and the other less highly trained who should practice in rural districts. Dr Phillips said that this was unthinkable. A doctor who was qualified to practice in the city was none too good for the rural dwellers.

Dr Phillips said that the modern standard of the practice of medicine required physicians to make periodic examinations of the children whom they bring into the world, to keep records of their progress and to urge the mothers to bring their children for examinations at regular intervals. It is entirely ethical that a physician should ask a mother to return with the child at a specified time, and if she does not come, to call her on the telephone and urge her to come. Physicians are not practicing up-to-date medicine unless they are teaching preventive medicine to their patients and families. Medical students should be taught how to instruct their patients in medical subjects. In closing, Dr Phillips condemned the attitude of some of the doctors who say to an applicant for a physical examination "I have known you all your life and you don't need an examination." The physician owes it to his confiding patients that he give them the benefits of a skillful examination. To do less is to neglect his best friends.

Dr Farrand continued the line of thought of Dr Phillips by saying "One of the greatest things a doctor must do is to accept leadership in public health. Doctors are not meeting that obligation, but there is a marked improvement. But doctors will not feel this obligation until the medical schools teach it to their students."

Mr George W Whiteside, former Counsel for the Medical Society of the State of New York, spoke on the provision of the Medical Practice Act by which the medical profession has become self-governing through the Grievance Committee.

Dr Elmer E Brown, Chancellor of the New York University, spoke on the subject "The Application of the Knowledge of Medicine" and said that New York University was a better institu-

tion because of the constructive criticisms of Dr Downing. He answered the charge that Dr Downing was a bureaucrat by showing that a bureaucracy was necessary in order to stabilize and perfect democracy. When the people adopt a progressive idea, the law that they enact places its execution in the hands of a department or bureau whose members must work out the details of entirely new methods of putting the law into effect, and the bureau not only inherits all the odium and opposition that existed during the campaign for the enactment of the law, but it also creates new opposition by excluding methods which the more radical group of proponents seek to have adopted.

Dr Brown considered that legislation is slowly improving in quality because legislators are showing an increasing willingness to listen to such bureaucrats as Dr Downing who knows his subject thoroughly, and is unwavering in his support of high standards. Dr Downing has always stood for high ideals and a faith which was the "Substance of things hoped for and the evidence of things not seen."

Dr Charles B. Alexander, senior member of the Regents Committee on Higher Education, said that the Board of Regents had adjourned its meeting for a week in order to attend this dinner. He presented Dr Downing with an engrossed set of resolutions expressing the regard of the meeting for the doctor on the completion of his fifty-two years of service in the cause of education.

Dr Downing talked in a personal way of his experiences and the fine cooperation he had always received from the leaders in all the professions with which he dealt. Referring to several allusions to his acumen as a politician, he said that at the outset of his career a much older friend had given him the advice to admit nothing, deny nothing, and explain nothing, and that he had tried to follow that advice.

When Dr Downing was made Director of Professional Education in 1908, he and the Regents had laid out a program for higher standards, of which the first fruits was the nursing law of 1912, and the last and greatest the Medical Practice Act of last spring.

Dr Downing referred feelingly to the opposition which he continually met in promoting the higher ideals of professional education, but he generously gave the credit of success to the associates who had worked with him. Those who have known Dr Downing personally, appreciate this generosity of his nature and his strict adherence to the standard that every progressive act shall be for the benefit of the people.

In closing Dr Downing said that the love and affection of his co-laborers had given him the best satisfaction of his life. He quoted Cicero as saying that to the elderly man two things were of special worth, first, virtue which included the courage of one's convictions, and second, friendship. "The meeting tonight," he said, "demonstrates that you are hearty supporters of my convictions and are my friends."

TRI-STATE CONFERENCE

A meeting of the Tri-State conference that was approved by the House of Delegates of the Medical Society of the State of New York, was held on December 4, in the office of the Medical Society of New Jersey, 22 Gramercy Court, Atlantic City, with Dr J. S. Greene, President of the New Jersey Society, presiding. The Conference is composed of the following officers from each state, the President, the President-elect, the Secretary, the Executive officer, the Chairman of the Board of Trustees and the Editor of the State Journal. Those present from the Medical Society of the State of New York were Dr George M. Fisher, President, Dr J. S. Lawrence, Executive Officer, Dr Frank Overton, Executive Editor, and Dr N. B. Van Etten, Chairman of the Committee on Nursing of the Medical Society of the State of New York and also of the American Medical Association.

From the New Jersey Medical Society there were present Dr James S. Greene, President, Dr Walt Conaway, First Vice-President, Dr H. O. Reik, Secretary and Editor.

From Pennsylvania there were Dr H. W.

Albertson, President, Dr C. N. Morgan, President-elect, Dr Frank Hammond, Editor, Dr Campbell, Epidemiologist, State Department of Health, and Mr C. S. Pitcher, Superintendent of the Presbyterian Hospital, Philadelphia.

Nursing was the first subject to be discussed, and was presented by Dr N. B. Van Etten of New York. Dr Van Etten, representing both New York State and the American Medical Association, brought a mass of correspondence and articles on nursing, on which he made running comments. While his committees had not formulated their conclusions or made definite recommendations, yet they had found certain general conditions throughout the land, the committees had found a great demand for what is called basic or fundamental nursing, in distinction from the more highly trained nurse in special fields, such as those of supervising, operating room technician, public health nurse, and those who follow specialties such as psychiatric nursing, and the care of eye cases. Especially is there a call for the woman who will give bedside care during a common disease, and will do for the patient those

things which he would do for himself if he were well, and in addition can carry out the common procedures which are ordered by the doctor. This kind of nurse is to be considered from the standpoint of the patient rather than that of the doctor, for it is not so much technical care that she is called upon to give, but rather the care that is asked for by the patient.

Dr Van Etten discussed some of the reasons for the shortage of nurses, one of which was the tendency of sick people in hospitals to demand special nurses as luxuries rather than necessities. Special nurses are glad to supply the demand, especially since the service is comparatively easy, the pay good and the conditions of service attractive owing to the company of other nurses. To meet the demands for the special nurses, the group system has been proposed, in which one nurse cares for two or more cases in adjoining rooms, but this plan is not popular among patients, although the doctors favor it.

It seemed to be the opinion of doctors that the shortage of nurses is not nearly so acute as it was a year or two ago.

Dr Van Etten also discussed what the nurses say "in defense of their attitude." The nurses enumerate the following points to be considered: The opportunities for employment in other fields open to women.

The meager financial reward for hard service.
Lack of incitement to action, since few high positions are open to nurses.

The comparatively poor pay for private nursing when lack of continuity of employment is considered.

Increase of nurses' pay is not in proportion to the increase in the cost of living.

Unpleasant conditions of work.

Long hours.

Sickness and loss of time is at the expense of the nurse.

Dr Van Etten closed with the suggestion that the conference express an opinion regarding the advisability of training a special group of nurses with a two-year course in the basic principles of bedside nursing. On the completion of the basic course, a nurse could take other courses which would fit her for a position as a supervisor, or in public health, or a nurse in a specialty, such as psychiatry, or eye, or genito-urinary work.

Dr Van Etten's suggestion received the general approval of the conferees, and it was their opinion that the plan for training the basic nurse should be developed in detail so that it may be presented to the training schools.

Mr C S Pitcher spoke by invitation from the standpoint of the hospital superintendent. He said that the profession of nursing had developed during the days of the development of modern medicine, and that while Louis Pasteur was developing a new technique for doctors, Florence Nightingale was developing the nurses who en-

abled the doctors to carry out their new technical standards.

Mr Pitcher described some of the experiments in the Presbyterian Hospital of Philadelphia, to carry out the group system of nursing and the plan of sending nurses to do hourly duty. While the experiments have been fairly successful from the hospital's point of view, yet they do not begin to solve the problems of private nursing.

Dr Frank Hammond, Editor of the *Atlantic Medical Journal*, showed how the nurse is now overtrained in some respects, and said that the hours spent in the study of chemistry were largely unnecessary in so far as they did not help the nurse to care for the patient.

Dr C W Morgan emphasized the need of more nurses who should conform to the patient's idea of what care a nurse should give. He asked the questions, "Who created the demand for the present higher education of the nurse, was it the nurse herself, or the doctor, or the public? Is the increasingly high standard of schools of nursing the result of the same system of investigation which resulted in cutting the number of medical schools in half within twenty years?"

A factor in raising the education of all trained nurses was the demand of surgeons and other specialists for the training of nurses to meet their own special requirements. But most persons who were sick and most doctors who treat these cases do not demand the higher educational qualifications, but are satisfied with the nurse who is basically trained in giving bedside care.

Dr H W Albertson spoke of some of the difficulties arising in connection with nursing in Pennsylvania, among them being the action of the State School authorities in sending nurses to the City of York to examine school children, and that of industrial plants in employing nurses to give treatment to injured workmen in excess of that required in first aid. He said that doctors had created the nurse, and that now the nurse had outgrown the doctor and was usurping his place. He agreed that the basic nurse was needed.

Dr George M Fisher outlined the investigations into the nursing problem conducted by the Medical Society of the State of New York.

In closing the discussion, Dr Van Etten proposed the following definition of the basic nurse.

The basic nurse is one who has graduated from a hospital training school after a two-year course in the theory, art, and practice of giving bedside nursing care to those incapacitated with ordinary surgical, medical, obstetrical, or pediatric conditions.

This definition was unanimously approved.

The control of rabies was presented by Dr H O Reik, Secretary of the Medical Society of New Jersey and Editor of its *Journal*, who read a brief paper written by Dr H S Costill, State

Director of Public Health for New Jersey While there is a current impression that human rabies is almost unknown, yet it causes from five to ten deaths annually in each of the three states, New Jersey, Pennsylvania, and New York Four preventive measures are used to control rabies in dogs

- 1 Preventive inoculations of dogs, with rabies virus
- 2 Muzzling dogs at large
- 3 The destruction of stray dogs
- 4 Quarantine against dogs from outside areas

A single preventive inoculation against rabies is effective for a year, in over 90 per cent of cases, yet experience has shown that it is not an effective public health measure, owing to the opposition of the people Quarantine, and muzzling are effective when they are carried out, and the people seem to observe these procedures more willingly than the inoculation law

One of the pleasing and profitable phases of the conference was the opportunity it afforded of meeting the men informally and hearing them tell how they have solved their own peculiar problems Dr Albertson told a small group how the Pennsylvania State Medical Society had purchased a building in Harrisburg for its headquarters by taking the money from its accumulated funds, and putting them in the building as an investment, whose rentals to outside parties give a six per cent interest return, besides providing quarters for the State Society

The *Atlantic Medical Journal*, the organ of the State Society, has a deficit of only about fifty cents per member Few fees to advertising agents are paid because the leaders go out and get the advertisements Dr Albertson quoted this fact as evidence of his claim that the physicians of the State of Pennsylvania were superior to those of most other states in their activity in behalf of their State Medical Society As evidence that the members take a deep interest in the County Medical Societies also, the doctor said that 48 out of the 63 county societies issued their own monthly publications Compare this record with that of New York State with only five publications by its county medical societies

The after dinner coffee and cigars afforded the opportunity for further informal talking in which it was developed that Pennsylvania keeps up the custom of receiving delegates from sister states At the last Annual Meeting representatives were received from six other states A cordial invitation was extended to New York to send its representatives to the next meeting The Secretary and Editor were also invited to the meeting of County Secretaries which is held during the Annual Meeting

Considerable discussion arose over the open hospital in the smaller towns The prevailing method in Pennsylvania is that of the closed hospital, owing to a system of state aid, while in New York, the open form of hospital prevailed This subject was suggested for the next meeting of the Conference, which will be held in New York City sometime in February

IN MEMORIAM, DR WILLIAM FRANCIS CAMPBELL

Memorial adopted by the Executive Committee of the Council of the Medical Society of the State of New York, November 11, 1926.

Again the Portals of the World Beyond have swung open to admit a Member of the House of Delegates, another chair is vacant at our Meetings, another warm grasp is cold, another cheery voice is never again to be heard, and another familiar face has become a memory

On September 7, 1926, in the midst of the activities of his chosen work the summons came to our friend and associate, Dr William Francis Campbell, to lay down the working tools of life, to leave the fields of earthly labor and repair to his Eternal Home, there to receive, if his mortal life may be taken as a criterion, the welcome commendation—"Well done good and faithful servant, enter thou into the joy of thy Lord."

For more than a quarter of a century Dr Campbell was closely identified with the Medical Society of the State of New York and his loyalty and sincere devotion to the welfare of its members and the ideals of the profession are well worthy of emulation

The sincerity and uprightness of his character, his optimistic enthusiasm, his courage in supporting measures he deemed just and right soon attracted the attention of his fellows and he received at their hands all the honors that the Society could bestow, becoming President in 1913, and serving as a delegate to the American Medical Association from 1915 to the date of his death

His courteous demeanor, his dignified yet cordial personality and his ever readiness to help in the work or assist a friend won the respect and esteem of all with whom he came in contact

Of his scientific attainments and his high standing in his chosen specialty it is unnecessary to speak, the well-merited reputation that he had gained is known to all

The Executive Committee of the Council deplores the loss the Society has sustained, and extends sincere sympathy to his family and friends

J. E. JENYINGS,
D. S. DOUGHERTY,
Committee

things which he would do for himself if he were well, and in addition can carry out the common procedures which are ordered by the doctor. This kind of nurse is to be considered from the standpoint of the patient rather than that of the doctor, for it is not so much technical care that she is called upon to give, but rather the care that is asked for by the patient.

Dr Van Etten discussed some of the reasons for the shortage of nurses, one of which was the tendency of sick people in hospitals to demand special nurses as luxuries rather than necessities. Special nurses are glad to supply the demand, especially since the service is comparatively easy, the pay good and the conditions of service attractive owing to the company of other nurses. To meet the demands for the special nurses, the group system has been proposed, in which one nurse cares for two or more cases in adjoining rooms, but this plan is not popular among patients, although the doctors favor it.

It seemed to be the opinion of doctors that the shortage of nurses is not nearly so acute as it was a year or two ago.

Dr Van Etten also discussed what the nurses say "in defense of their attitude." The nurses enumerate the following points to be considered: The opportunities for employment in other fields open to women.

The meager financial reward for hard service.

Lack of incitement to action, since few high positions are open to nurses.

The comparatively poor pay for private nursing when lack of continuity of employment is considered.

Increase of nurses' pay is not in proportion to the increase in the cost of living.

Unpleasant conditions of work.

Long hours.

Sickness and loss of time is at the expense of the nurse.

Dr Van Etten closed with the suggestion that the conference express an opinion regarding the advisability of training a special group of nurses with a two-year course in the basic principles of bedside nursing. On the completion of the basic course, a nurse could take other courses which would fit her for a position as a supervisor, or in public health, or a nurse in a specialty, such as psychiatry, or eye, or genito-urinary work.

Dr Van Etten's suggestion received the general approval of the conferees, and it was their opinion that the plan for training the basic nurse should be developed in detail so that it may be presented to the training schools.

Mr C S Pitcher spoke by invitation from the standpoint of the hospital superintendent. He said that the profession of nursing had developed during the days of the development of modern medicine, and that while Louis Pasteur was developing a new technique for doctors, Florence Nightingale was developing the nurses who en-

abled the doctors to carry out their new technical standards.

Mr Pitcher described some of the experiments in the Presbyterian Hospital of Philadelphia, to carry out the group system of nursing and the plan of sending nurses to do hourly duty. While the experiments have been fairly successful from the hospital's point of view, yet they do not begin to solve the problems of private nursing.

Dr Frank Hammond, Editor of the *Atlantic Medical Journal*, showed how the nurse is now overtrained in some respects, and said that the hours spent in the study of chemistry were largely unnecessary in so far as they did not help the nurse to care for the patient.

Dr C W Morgan emphasized the need of more nurses who should conform to the patient's idea of what care a nurse should give. He asked the questions, "Who created the demand for the present higher education of the nurse, was it the nurse herself, or the doctor, or the public? Is the increasingly high standard of schools of nursing the result of the same system of investigation which resulted in cutting the number of medical schools in half within twenty years?"

A factor in raising the education of all trained nurses was the demand of surgeons and other specialists for the training of nurses to meet their own special requirements. But most persons who were sick and most doctors who treat these cases do not demand the higher educational qualifications, but are satisfied with the nurse who is basically trained in giving bedside care.

Dr H W Albertson spoke of some of the difficulties arising in connection with nursing in Pennsylvania, among them being the action of the State School authorities in sending nurses to the City of York to examine school children, and that of industrial plants in employing nurses to give treatment to injured workmen in excess of that required in first aid. He said that doctors had created the nurse, and that now the nurse had outgrown the doctor and was usurping his place. He agreed that the basic nurse was needed.

Dr George M Fisher outlined the investigations into the nursing problem conducted by the Medical Society of the State of New York.

In closing the discussion, Dr Van Etten proposed the following definition of the basic nurse.

The basic nurse is one who has graduated from a hospital training school after a two-year course in the theory, art, and practice of giving bedside nursing care to those incapacitated with ordinary surgical, medical, obstetrical, or pediatric conditions.

This definition was unanimously approved.

The control of rabies was presented by Dr H O Reik, Secretary of the Medical Society of New Jersey and Editor of its Journal, who read a brief paper written by Dr H S Costill, State

Director of Public Health for New Jersey While there is a current impression that human rabies is almost unknown, yet it causes from five to ten deaths annually in each of the three states, New Jersey, Pennsylvania, and New York Four preventive measures are used to control rabies in dogs

- 1 Preventive inoculations of dogs, with rabies virus
- 2 Muzzling dogs at large
- 3 The destruction of stray dogs
- 4 Quarantine against dogs from outside areas

A single preventive inoculation against rabies is effective for a year, in over 90 per cent of cases, yet experience has shown that it is not an effective public health measure, owing to the opposition of the people Quarantine, and muzzling are effective when they are carried out, and the people seem to observe these procedures more willingly than the inoculation law

One of the pleasing and profitable phases of the conference was the opportunity it afforded of meeting the men informally and hearing them tell how they have solved their own peculiar problems Dr Albertson told a small group how the Pennsylvania State Medical Society had purchased a building in Harrisburg for its headquarters by taking the money from its accumulated funds, and putting them in the building as an investment, whose rentals to outside parties give a six per cent interest return, besides providing quarters for the State Society

The *Atlantic Medical Journal*, the organ of the State Society, has a deficit of only about fifty cents per member Few fees to advertising agents are paid because the leaders go out and get the advertisements Dr Albertson quoted this fact as evidence of his claim that the physicians of the State of Pennsylvania were superior to those of most other states in their activity in behalf of their State Medical Society As evidence that the members take a deep interest in the County Medical Societies also, the doctor said that 48 out of the 63 county societies issued their own monthly publications Compare this record with that of New York State with only five publications by its county medical societies

The after dinner coffee and cigars afforded the opportunity for further informal talking in which it was developed that Pennsylvania keeps up the custom of receiving delegates from sister states At the last Annual Meeting representatives were received from six other states A cordial invitation was extended to New York to send its representatives to the next meeting The Secretary and Editor were also invited to the meeting of County Secretaries which is held during the Annual Meeting

Considerable discussion arose over the open hospital in the smaller towns The prevailing method in Pennsylvania is that of the closed hospital, owing to a system of state aid, while in New York, the open form of hospital prevailed This subject was suggested for the next meeting of the Conference, which will be held in New York City sometime in February

IN MEMORIAM, DR WILLIAM FRANCIS CAMPBELL

Memorial adopted by the Executive Committee of the Council of the Medical Society of the State of New York,
November 11, 1926

Again the Portals of the World Beyond have swung open to admit a Member of the House of Delegates, another chair is vacant at our Meetings, another warm grasp is cold, another cheery voice is never again to be heard, and another familiar face has become a memory

On September 7, 1926, in the midst of the activities of his chosen work the summons came to our friend and associate, Dr William Francis Campbell, to lay down the working tools of life, to leave the fields of earthly labor and repair to his Eternal Home, there to receive, if his mortal life may be taken as a criterion, the welcome commendation—"Well done good and faithful servant, enter thou into the joy of thy Lord"

For more than a quarter of a century Dr Campbell was closely identified with the Medical Society of the State of New York and his loyalty and sincere devotion to the welfare of its members and the ideals of the profession are well worthy of emulation

The sincerity and uprightness of his character, his optimistic enthusiasm, his courage in supporting measures he deemed just and right soon attracted the attention of his fellows and he received at their hands all the honors that the Society could bestow, becoming President in 1913, and serving as a delegate to the American Medical Association from 1915 to the date of his death

His courteous demeanor, his dignified yet cordial personality and his ever readiness to help in the work or assist a friend won the respect and esteem of all with whom he came in contact

Of his scientific attainments and his high standing in his chosen specialty it is unnecessary to speak, the well-merited reputation that he had gained is known to all

The Executive Committee of the Council deplores the loss the Society has sustained, and extends sincere sympathy to his family and friends

DIPHTHERIA PREVENTION PLACARD

A placard to be hung in doctors' offices has been designed by the State Committee to eradicate diphtheria. It measures nine by eleven inches, and is available to every physician in the state

against diphtheria by immunization with toxin-antitoxin

"We hope that your Society will take advantage of this offer by the Tuberculosis Committee. Enclosed is a suggestion as to how application may be made to the Secretary of your Local Tuberculosis and

PLACARD FOR PHYSICIANS' OFFICES

The placard is approved by the Medical Society of the State of New York through its representatives on the central committee, and by the President, Dr. George M. Fisher, through the following open letter

"November 19, 1926

"My dear Doctor

"Attached is a printer's proof, reduced size, of a diphtheria prevention placard which has been especially designed for use in physicians' offices throughout the state in connection with the campaign to eradicate diphtheria. The placard is supplied free through the State and Local Committees on Tuberculosis and Public Health of the State Charities Aid Association, and was developed in cooperation with the State Society. It is decidedly attractive, being printed in black on a buff background, has rounded corners, with a perforation at the top for convenience in hanging

"The placard is designed especially for hanging in the physician's office to serve as a reminder to the parents of small children that they can be protected

Public Health Committee. When making application for placards, be sure to state the number of members in your Society

"If your Society will not meet again before Christmas, the matter might be considered by your Comitia Minora

"Very truly yours,

"GEORGE M. FISHER,

"President."

The physicians of Buffalo and other places have used similar placards with the approval of their medical societies. The one reproduced here is distributed free by the local Committee on Tuberculosis and Public Health of each county. It is hoped that every doctor will secure one for display in his office, thereby demonstrating his confidence in the preventive measure, and his interest in the welfare of his patients. Publicity in regard to the toxin-antitoxin immunization will hasten the adoption of the preventive measure

THE ANNUAL MESSAGE OF PRESIDENT COOLIDGE

President Coolidge's message of December 8th accompanying his proposed budget of expenses to Congress contains two paragraphs of great interest to physicians and layworkers. Regarding the Sheppard-Towner funds he writes:

"No estimate is submitted for carrying on the work under the maternity and infancy act, approved November 23, 1921, inasmuch as the authorization of appropriations for this purpose was fulfilled with the appropriation for 1927. A bill is now pending before the Congress extending the provisions of that act to the fiscal years 1928 and 1929. If and when that measure becomes law, I propose sending to the Congress a supplemental estimate for an appropriation to make its provisions effective. I am in favor of the proposed legislation extending the period of operation of this law with the understanding and hope that the administration of the funds to be provided would be with a view to the gradual withdrawal of the Federal government from this field, leaving to the states, who have been paid by Federal funds and schooled under Federal supervision, the privilege and duty of maintaining this important work without aid or interference from the Federal government.

"I have referred in previous budget messages to the advisability of restricting and curtailing Federal subsidies to the states. The maternity act offers concrete opportunity to begin this program. The states should now be in a position to walk

alone along this highway of helpful endeavor and I believe it in the interest of the states and the Federal government to give them the opportunity."

The second health topic in the message refers to tuberculosis in cattle and is as follows:

"For the eradication of tuberculosis in animals an estimate of \$5,853,000 is included in the budget. This is an increase of \$1,200,000 over the amount provided for the current year. The continuing increase in the number of cities which have placed embargoes against milk from dairy herds which have not passed the Federal tuberculin test is placing a heavy burden on the owners of dairy herds, since slaughter of infected animals is the accepted method of eradication. The furnishing of pure milk is of vital importance to the health of the people. Because of its interstate character it is entirely proper that the Federal Government share with the states the cost of protecting the purity of this great food supply. The amount included in the estimates should permit adequate prosecution of the work of eliminating tubercular cattle from dairy herds. The results of the work already done warrant the belief that we can confidently expect the complete elimination of this menace to health. With this hope and probability in mind, there certainly is no excuse or warrant for state or nation to withhold the funds necessary to effectively carry on this important campaign."

REGISTRATION

Twelve thousand physicians have registered with the State Department of Education in accordance with the new Medical Practice Act. This is three-fourths of the legal practitioners of medicine of New York State. But there still remain four thousand doctors who have not registered.

Many of those who have not registered are merely dilatory. They have received their cards from the Department of Education and have read

the directions in this Journal. They have laid both aside and now they can't find them.

The doctors are not refusing to register—they are just a bit careless. If you have not yet registered, write at once to the Board of Medical Examiners, State Department of Education, Albany, N. Y., and ask for a registration blank. The procedure of filling out the blank is simple and will not take ten minutes of any doctor's time. Register now.

ESSEX COUNTY MEDICAL SOCIETY

There were thirteen members present at the annual meeting of the Medical Society of the County of Essex, on November 16. The new officers elected are as follows:

President, Dr. W. T. Sherman, Crown Point, N. Y.; Vice-President, Dr. J. H. Evans, Keeseville, N. Y.; Secretary-Treasurer, Dr. L. H. Gaus, Ticonderoga, N. Y.

The scientific program consisted of a paper entitled "Hyperthyroidism and Incipient Pulmonary Tuberculosis, a Comparative Study," by Dr.

H. J. Harris of Westport. X-ray studies of the conditions described in the paper were shown by Dr. J. P. J. Cummins and Dr. M. E. Sargent.

An unusual case history was reported by Dr. Dowd. Dr. Cummins and Dr. Gaus—that of an abdominal carcinomatosis in a man of 27, with unusual clinical symptoms. This aroused much interest and was well discussed.

A very agreeable luncheon was served by the hospital staff at the Moses-Ludington Hospital following the scientific program.

DIPHTHERIA PREVENTION PLACARD

A placard to be hung in doctors' offices has been designed by the State Committee to eradicate diphtheria. It measures nine by eleven inches, and is available to every physician in the state

It is hoped that every doctor will secure one for display in his office, thereby demonstrating his confidence in the preventive measure, and his interest in the welfare of his patients. Publicity in regard to the toxin-anti-toxin immunization will hasten the adoption of the preventive measure

The largest and best known of the endowments are probably those having to do with public health, especially those phases which a group of persons or a whole community must carry on. The Carnegie Foundations have concerned themselves largely with scientific researches, but many lines of research extend into the fields of medicine, that into heredity, for example.

The Rockefeller Foundation has extended its activities over the whole world, and has accomplished wonders in the control of hookworm, yellow fever, plague, cholera, and other devastating diseases. Its greatest work has been that of inducing the local states and communities to assume the work after its practicality has been demonstrated.

The Sage Foundation is showing communities how to deal with conditions of a social nature. It is concerned with such questions as poverty, housing, transportation, city planning, all of which have definite effects on health.

The Commonwealth Fund makes studies regarding children, and supports clinics for the detection of mental defects and the correction of abnormal behavior.

The work of the Milbank Foundation is of peculiar interest to physicians at the present time, because it is conducting three demonstrations of the application of modern methods of disease prevention and health promotion,—one in a rural

county, one in a second class city, and still another in a section of the American Metropolis. It is to the credit of the officials of these communities that they are recognizing the value of the demonstrations and are assuming a considerable share of their activities.

There is one phase of public health activity which the foundations have scarcely touched, and that is the development and demonstration of practical ways by which physicians in private practice may discharge their civic duties along medical lines. Doctors and lay workers both reiterate the assertion that the family doctor is the greatest factor in public health work. This Journal has frequently expressed the belief that the medical societies of the counties and the State are the natural means through which civic medicine may be practiced, but time and personal service are required to develop and institute the methods of the practice. It would seem that this is a field which the foundations could enter. There is a reluctance on the part of the medical societies to the acceptance of gifts from the foundations, and there is also a hesitation on the part of the leaders in the foundations to giving the control of their funds to the medical societies. But these obstacles are by no means insuperable. More than one county medical society in New York is administering funds supplied by lay organizations, and are doing it to the satisfaction of the givers, the doctors, and the communities.

SERUM FOR SNAKE VENOM

Supplementing the report on serum for snake venom as given in this JOURNAL for August 15, 1926, page 729, attention is called to an item in the *New York Times* for October 8 in regard to the production of the serum in the United States. The report says:

"Nine rattlers and a large number of moccasin snakes were used yesterday to help produce American made anti-snake serum, an enterprise on which Dr. Amaral is working at the Mulford Company laboratories at Glenolden, Pa. The importation of anti-snake serum from Brazil is forbidden, according to a regulation of the United States Public Health Service, and Dr. Amaral is working in cooperation with Dr. Thomas Barbour of Harvard, the United Fruit Company and the Mulford laboratories to produce an American supply. In about four months, said Dr. Ditmars yesterday, there should be an American supply sufficient for all emergencies.

"Yesterday afternoon the snakes were brought in heavy ashcans into a room where Dr. Ditmars and Dr. Amaral had prepared a simple extracting apparatus. A rubber diaphragm was stretched across the top of a small vial, and the whole apparatus screwed to a table. The snakes were allowed to plunge their fangs into the rubber and the venom was caught in the vial."

Items such as this are valuable for two reasons:

- 1 They are up-to-date sources of information to the physician regarding the serum and where to obtain it.

- 2 They educate the people regarding the means of relief in an emergency caused by snake bites.

We wonder how the tabloid dailies missed the heroic doctors obtaining the serum. Of course the scientists had not advertised their plans.

THE DAILY PRESS

DEADLY SPORT

Hunting has come to be recognized as a deadly form of sport, according to the *New York Sun* for November 26 and 29. The New York State Conservation Commission has issued a report on the number of casualties reported during the month ending November 15, 1926, in New York State. The report shows that 15 persons were killed and 62 wounded while hunting during the month.

The report also shows that 650,000 licenses for hunting and fishing had been issued during the year. If this number of persons were exposed to the dangers incident to hunting, the death and casualty rates may be computed. Since 600,000 were engaged in hunting, and 77 casualties occurred, the casualty rate was 12.5 per 100,000 per month, or 150 per year. But not all the 600,000 were engaged in hunting during the month, and the actual casualty rate would therefore be much higher than that given. Statisticians will derive some comfort from the fact that the casualty rate for 1926 was only 75 per cent of that for 1925, when 29 persons were killed and 86 wounded.

The immediate causes of the 15 deaths were as follows:

Shot by companions	11
Accidents from own gun	2
Drowned	1
Heart failure while dragging a deer carcass	1

The proportion of killed to wounded,—1 to 4,—is about that which occurs in a battle. It may be presumed that the causes of the wounds are the same as those of death.

The causes of death among hunters are evidently carelessness and inexperience. The obvious remedies are therefore, 1, the exclusion of the

unfit by a system of licensing, and 2, the limitation of armaments after the manner of the national pacifists.

The licensing system applied to hunting is a failure as great as that of liquor selling. Every would-be hunter knows that the other fellow is careless, while he himself will surely be careful. No system of examination will ensure carefulness and thoughtfulness in the presence of prospective game.

The limitation of the use of fire arms has never been popular owing to the excessive development of the idea of personal independence. It is not creditable to the intelligence of American people that each individual should assert his right to do what he is forbidden to do by a law enacted for the good of all.

The only effective preventive measure against casualties from hunting is education. Killing wild life can no longer be justified by the need for protection against their depredations. The preservation of wild birds, fish and animals is demanded in every argument for getting people "Back to nature." The hunting instinct is too deeply imbedded in human nature to be eradicated under any conditions that are now in sight. How then may it be intelligently directed?

One evident answer is, by hunting with a camera instead of a gun. Shooting with a camera has all the zest of gun shooting, and it has the advantage of safety to everybody, including the animals and birds that are hunted.

The Boy Scouts movement, with its camping and nature study, will be a great factor in the development of the modern civilized system of hunting in which the camera is substituted for the gun.

PUBLIC HEALTH FOUNDATIONS

Physicians are interested in the great endowments for the promotion of progress, physical, mental, and moral. The great purposes of the endowments are, 1, the discovery of new truths, and 2, the application of the truths to the daily lives of people.

The *New York Times* of November 27 comments editorially on the report of Dr. F. P. Keppeler, President of the Carnegie Corporation. This report refutes a prevalent belief that since the larger foundations have supported various lines of work, other would-be donors have failed to

give. The facts are quite the contrary. It has been one of the basic conditions of gifts from the foundations that whenever a new line of activity has been undertaken, the foundation would carry it on as a demonstration with the expectation that the proper authorities would support and extend it when its value was assured. A typical example has been that of anti-meningitis serum. The Rockefeller Institution developed the methods of producing and applying the serum, and then gave its production and sale over to boards of health and reputable commercial houses.

The largest and best known of the endowments are probably those having to do with public health, especially those phases which a group of persons or a whole community must carry on. The Carnegie Foundations have concerned themselves largely with scientific researches, but many lines of research extend into the fields of medicine, that into heredity, for example.

The Rockefeller Foundation has extended its activities over the whole world, and has accomplished wonders in the control of hookworm, yellow fever, plague, cholera, and other devastating diseases. Its greatest work has been that of inducing the local states and communities to assume the work after its practicality has been demonstrated.

BOOK REVIEWS

MEDICAL CLINICS OF NORTH AMERICA Volume 9 Number 1, July, 1925 (St. Louis Number) Published every other month by the W. B. Saunders Co., Philadelphia and London Per Clinic Year (6 issues) Cloth, \$16.00, Paper, \$12.00

The catholicity of subjects discussed in this number, makes it unusually interesting. "The Dietetic Management of Renal Disease" is considered fully, but it is to be regretted that complete data was not furnished with each case. Such information would be of value to another physician when attempting to confirm the writer's observations. On page 73 there is evidently a mistake in the calculation of the quantity of sugar in the body of the patient under consideration. As a principle is being demonstrated in this case, it is well for readers to note the error.

Volume 9, Number 2, September, 1925 (New York Number)

This number contains an interesting article on Physical Therapy in Chronic Arthritis. The impression is left that physical therapy is purely a treatment and nothing definite is to be promised to the patient. Heart disease, gall bladder disease, pulmonary syphilis, and nephritis are considered from various standpoints. "The Nervous Run Down Patient" comes up for consideration, but the patient is left where he began. All of the treatments recommended give such patients little or no relief. This subject opens a wide field and more frequent excursions into it will add much of interest to medical literature. It is the reviewer's impression that the modern novelists understand such patients much better than physicians. The number as a whole is decidedly worthwhile.

Volume 9, Number 3, November, 1925 (New York Number)

The standard of interest characteristic of this publication is maintained in this number. Most of the topics considered are timely and the cases and statistical data are ample to illustrate the subject under discussion. As fruitless as the exploitation of the possible foci of infection in the nose, throat, and accessory sinuses, has been, one writer presents a possible utopia by more widespread manipulations in this area. With reference to the article on "Focal Infection" we think, it has been the experience of most every physician who keeps records of patients, that the day has passed when one should consider foci of infection of paramount importance. Many patients are parading themselves in the offices of physicians who have had all possible foci removed, yet they are sick. They are either suffering from a disease of unknown etiology, nervousness, or an incurable disease of known etiology. A physician should experience the same sense of embarrassment when speaking inclusively of focal infection, as when listening to some one talking on the dangers of perpetually chronic appendicitis.

Volume 9, Number 4, January, 1926 (Tulane University Number)

This number contains articles on thirty-five different subjects. All of the articles contain information of value to the physician. Tropical diseases are discussed, as well as those of universal distribution. The article on "Unusual Manifestations of Heart Disease" will be of interest to surgeons as well as physicians.

Volume 9, Number 5, March, 1926 (Chicago Number)

This number contains several articles on angina pectoris, consisting of case reports and discussions. There is no mention made of the operative treatment of this condition, and evidently it has been discontinued in Chicago. There is an interesting article on a case of hyperthyroidism, which was supposed at one time in the history of the trouble to alternate with hypothyroidism or myxedema. One sees mention frequently in the literature of these two conditions existing simultaneously in the same patient. This is because authors have probably never examined a thyroid gland at autopsy from a patient with true myxedema, because if they had they would have found that so much of the thyroid tissue had disappeared that there was not enough of the gland left to produce a hyper amount of the thyroid secretion, normal, or otherwise. There is an interesting case of cerebral hemorrhage with hyperglycemia and glycosuria presented.

Volume 9, Number 6, May, 1926 (Chicago Number)

This number contains a number of unusually interesting articles, and one that is of value to anyone examining patients, as it gives the ground work for the study of neurologic cases. One of the author succumbs to one of the common tendencies of this day in medical literature, namely, to tell his audiences that he is an expert. The article on "Disability, Damages or Disease" is noteworthy, as the author discusses a group of case types that are very trying to physicians everywhere. Singer's article on rare diseases of the stomach calls attention to frequently forgotten disease entities.

J. ARTHUR BUCHANAN

DISEASES OF THE SKIN By RICHARD L. SUTTON, M.D. LL.D., F.R.C. Sixth edition, revised and enlarged. Octavo of 1303 pages, with 1147 illustrations, and 11 colored plates. St. Louis, C. V. Mosby Company 1926. Cloth, \$12.00.

This edition of Sutton's excellent book follows only two years after his previous edition, but its publication has been necessitated by the advances made in Dermatology during that period. The author has included, for the first time, a few of the rarer, or more recently discovered, dermatoses, which include the dermatological aspect of rat-bite fever, ulcer vulvae actum, and others. Syphilis has taken up about eighty-five pages of the text, and while the author appreciates that this is not an exhaustive treatment of the disease, what he has written on the subject is extremely lucid, and up to the minute.

The book is well written, in a style which makes for easy reading, printed in good type on excellent paper, and is copiously illustrated. The reviewer believes it to be one of the real good books on Dermatology today.

E. ALMORE GAUVAIN

DISEASES OF CHILDREN A Short Introduction to Their Study. By HECTOR CHARLES CAMERON, M.A., M.D. 16mo of 199 pages. London and New York, Oxford University Press, 1926. Cloth \$1.75 (Oxford Medical Publications).

As the writer claims, this is no systematic presentation of Pediatrics or any portion of it. It is almost a conversational presentation of certain aspects of it.

The reviewer enjoyed the reading of it and agrees with the author's views as fully as anyone who thinks, is apt to agree with another, we differ in some items.

If the younger or any practitioner will carry this in his pocket—it is easy pocket size—and read it from time to time he will get value.

W. D. L.

INDEX—VOL. 26, 1926
